Reactivity of Superoxide Ion with Halogenonitriles and Dihalocarbons in Aprotic Media

Seungwon Jeon* and Yong-Kook Choi

Department of Chemistry, Chonnam National University, Kwang-ju 500-757, Korea Received July 10, 1995

The reactivity of superoxide ion (O_2^{-1}) with halogenated substrates is investigated by cyclic voltammetry and rotated ring-disk electrode method in aprotic solvents. The more positive the reduction potential of the substituted nitrile, the more facile is nucleophilic displacement by O_2^{-1} . The reaction rates of halogenonitriles with O_2^{-1} . vary according to the leaving-group propensity of halide (Br>Cl>F). The relative reaction rates of other substituted nitriles are in the order of electron-withdrawing propensity of the substituent group (CN>C(O)NH₂>Ph_{\approx}CH₂CN). The reaction of O_2^{-1} with dihalocarbons indicates that five-membered rings can be rapidly formed by the cyclization of substrate and O_2^{-1} , and the relative rates of cyclization depend on the number of methylenic carbons {Br(CH₂)_nBr, [n=1<2<3>4 >5]}. Mechanisms are proposed for the reaction of O_2^{-1} with halogenated substrates.

Introduction

The chemistry and reactivity of superoxide ion (O2-) interest chemists and biochemists because O2- is a respiratory intermediate¹ and an effective nucleophile in aprotic media.² In aprotic media stable solutions of O_2^{-1} can be prepared by electrochemical^{3~7} and chemical^{8~12} reduction of dioxygen. Although O_2^{-1} is a powerful nucleophile in aprotic media, it is deactivated in water because of its large hydration energy (~100 kcal) and rapid hydrolysis and disproportionation.13.14 The reactivity of O2" with alkyl halides via nucleophilic substitution in aprotic solvents was first reported in 1970.15.16 These and subsequent kinetic studies confirm that the reaction is first order in substrate in aprotic media,¹⁷⁻¹⁹ that the attack by O2^{-,} results in inversion of configuration.²⁰⁻²⁵ Polyhalogenated aromatic hydrocarbons [e.g., hexachlorobenzene (C6Cl6) and polychlorobiphenyls (PCB's)] are rapidly degraded by superoxide ion to bicarbonate and halide ions in aprotic solvents.²²⁶ Vicinal dibromoalkanes react with O_2^{-1} to produce products of carbon-carbon bond cleavage.²⁷ It has proposed that superoxide ion reacts with nitriles by proton abstraction²⁸ and by nucleophilic addition,²⁹ and that nitrile reacts with hydroperoxide ion (HOO⁻) or HO⁻ that is generated from the disproportionation of superoxide ion by water.^{30,31} The possibility of a nitrile reaction via the addition of superoxide ion to its triple bond cannot be fully excluded. In fact, NaO₂ converts aliphatic and aromatic nitriles into the corresponding amides.²⁰ The rate for the (HOO-+CH₃CN) reaction is faster than that for the (HO⁻ + CH₃CN) reaction;³⁰ ROO⁻ can also convert nitriles to amides.³² The present study has been directed to the evaluation of the reactivity of electrogenerated O₂⁻⁻ with halogenonitriles and dihalocarbons $[X(CH_2)_nX, X=Br \text{ or } Cl, n=2-6].$

Experimental

Dimethylformamide (DMF, 0.012% H_2O), and acetonitrile (MeCN, 0.002% H_2O) (Burdick and Jackson Laboratories, "distilled in glass" grade) were used as aprotic solvents and were kept free of dioxygen under an argon atmosphere. Tetraethylammonium perchlorate [TEAP(Et_4NClO_4)] from G. F.

Smith Chemicals was vacuum-dried over P_2O_5 for 24 hours prior to use as the supporting electrolyte (0.1 M TEAP). Bromoacetonitrile (BrCH₂CN), 2-bromopropionitrile (BrCH-MeCN), and malononitrile (CNCH₂CN) were used without further purification. All other solvents and chemicals were analytical grade or highest purity available and were used as received.

The cyclic voltammetric measurements were accomplished with a three electrode potentiostat (EG & G Prinston Applied Research model 273). The electrochemical measurements were made with a microcell assembly (10-mL capacity) that was adapted to use a platinum (area, 0.023 cm²) or a glassycarbon (area, 0.06 cm²) inlay working electrode, a platinumwire auxillary electrode (contained in a glass tube with a medium-porosity glass-frit and filled with a concentrated solution of supporting electrolyte), and a Hg/Hg₂SO₄ (sat'd K₂ SO₄) (+0.40 V vs SCE) was used as the reference electrode. Rotating ring-disk experiments were conducted with a bipotentiostat (EG & G Prinston Applied Research model 366A). A glassy carbon disk/platinum ring electrode was used. The electrochemical cell assembly was treated with HNO3 overnight and repeatedly soaked in a distilled water bath, and oven-dried at 140 °C for several hours. The electrode surfaces were polished with alumina and Buehler finest quality microcloth immediately prior to each experiment.

The apparent reaction rates for superoxide ion with the various substrates were determined from cyclic voltammetric peak-current measurements³³ and rotating ring-disk electrode method.³⁸ The reaction stoichiometry of superoxide ion per substrate (O_2^-/S) was determined by adding a known amount of substrate to a known excess of O2- in aprotic solvents. The unreacted O2- was assayed by anodic voltammetry. The reaction products from the stoichiometric combination of O_2^{-1} and substrates were characterized by cyclic voltammetry, UV-VIS spectroscopy, GC, and GC-MS. Halideion products were assayed by AgNO₃ titration. For the potentiometric titration of halide ion, 10 mL of distilled water and 0.5 mL of 98% of H₂SO₄ were added to the 10-mL aprotic solution. Argon gas was introduced continuously into the solution during the titration. Cyanate ion in the reaction mixture was quantitatively assayed by a spectrophotometric me-

Results and Discussion

Reactivity of O_2^{-1} with Halogenonitriles. Figure 1 illustrates the cyclic voltammetry of dioxygen (O_2) [curve a] and of BrCH₂CN [curve b] at a glassy-carbon electrode in dimethylformamide [0.1 M Et₄N(ClO₄)]. Halogenonitriles exhibit a single irreversible two-electron reduction in aprotic solvents (Table 1). Their effect on the electrochemical reduction of O_2 is illustrated in Figure 2. The cathodic peak current ($i_{b,c}$) for O_2 increases and the anodic peak current ($i_{b,c}$) for O_2 increases. This is consistent with the effect of alkylhalides in general and is the result of a reaction between O_2^{-1} and halogenonitriles. The anodic peaks at ± 0.75 V and ± 1.00 V vs SCE after a negative scan to ± 2.5 V indicate that Br⁻ and Cl⁻, respectively, are produced from the O_2^{-} /substrate reaction. In MeCN, the halogenonitriles

Figure 2. Effect of halogenoacetonitriles on the cyclic voltammograms of 1 mM O₂ at a GC electrode in DMF. (a) BrCH₂CN, (b) CICH₂CN, and (c) NCCH₂CN. 0.1 M Et₄NCIO₄, scan rate 0.1 V s⁻¹.

give a single cathodic peak at almost the same potential as in DMF. Controlled-potential reductive electrolysis of O_2 in the presence of excess Br(R)CHCN (R=H or Me) yields Br⁻, NCO⁻, and aldehyde [RCH(O)]. The apparent reaction rates for O_2^{--} with halogenonitriles are determined from cyclic voltammetric peak-current measurements.³³ The reaction stoichiometry of superoxide ion per substrate (O_2^{--}/S) was determined by adding a known amount of substrate to a known excess of O_2^{--} in aprotic solvents. The unreacted O_2^{--}

was assayed by anodic voltammetry. Meanwhile, the apparent pseudo-first order rate constants for O_2^{--} with the halogenonitriles are confirmed by the rotating ring-disk electrode technique; O_2 is reduced at the disk to O_2^{--} which reacts with substrate, and the unreacted O_2^{--} is oxidized at the ring electrode. The reaction stoichiometry is two electrons (2 O_2^{--}) per substrate molecule of Br(R)CHCN (R=H or Me). The stoichiometries and kinetics for the reactions between O_2^{--} and substituted nitriles (RCN) are summarized in Table 1. The reactivity of O_2^{--} with halogenonitriles in MeCN is about one-fourth of that in DMF. The overall reaction stoichiometry and products from the combination of O_2^{--} and the bromonitriles [Br(R)CHCN, R=H or Me] in aprotic solvents are represented by Eq. 1 (Table 1).

$$Br(R)CHCN+2 O_2^{-1} \rightarrow RCH(O)+Br^-+O_2+NCO^-$$
(1)

Because half of the Br(R)CHCN remains unreacted from a 1:1 Br(R)CHCN/O₂⁻⁻ combination, the primary step must be rate limiting and followed by a rapid step that consumes a second O₂⁻⁻. A reasonable reaction sequence (Scheme 1a) is nucleophilic attack of the halocarbon by O₂⁻⁻ with displacement of halide ion as the rate-limiting step. The resulting peroxyl radical is reduced by a second O₂⁻⁻ to peroxide ion. The resulting peroxide ion attacks the adjacent cyano group to give a dioxetanimine intermediate *via* intramolecular ring formation, which homolytically dissociates to an aldehyde and a cyanate ion.²⁷ Neighboring group participations are well known and the related intramolecular four-membered ring formation is 10²-10³ times as fast as the intermolecular reaction.³⁶

The electrochemical reduction of O_2 in the presence of NCCH₂CN exhibits a unique prewave in addition to the regular quasi-reversible couple (Figure 2). The new peak increases in height and shifts to more negative potentials with increasing concentrations of NCCH₂CN, and finally merges with the regular O_2/O_2^{-1} couple. The effective pK_4 values for nitriles and related compounds in DMF are summarized in Table 2.³⁵ Because the reaction rate between CNCH₂CN and O_2^{-1} is faster than that of PhCH₂CN, the primary path

must be a Brønsted acid-base reaction to give CNCHCN, which is stable in the presence of O_2 and reacts with water to regenerate CNCH₂CN. NCCH₂CN also reacts with HOO⁻ (generated by the disproportionation of O_2^{-1} with water) to give NCCH₂C(O)NH₂ ($E_{p,a}$, +0.14 V vs SCE; $\varepsilon_{251 \text{ nm}} = 15 \text{ mM}^{-1} \text{ s}^{-1}$ for its anion). The new prepeak for O_2 reduction in the presence of NCCH₂CN (Figure 2) probably is due to the latter's Brønsted acidity towards O_2^{-1} . An analogous prepeak for O_2 reduction is observed in acidified dimethyformamide.³⁷ Malononitrile ($\phi K_a' = 15.6$ in DMF) reacts with O_2^{-1} to give CNCHCN ($E_{p,a} = +0.40 \text{ V vs SCE}$, $\varepsilon_{226 \text{ nm}} = 21 \text{ mM}^{-1}\text{cm}^{-1}$), which is stable in the presence of O_2

$$NCCH_2CN + O_2^{-1} \rightleftharpoons NCCHCN + HOO \cdot$$
(2)

$$HOO \cdot + O_2^{-} \rightarrow HOO^- + O_2 \tag{3}$$

However, the resultant HOO⁻ reacts with NCCH₂CN via nucleophilic addition followed by internal proton transfer to produce NCCH₂C(OO⁻)NH. In turn the product hydrolyzes to give NCCH₂C(O)NH₂ (mp 122 $^{\circ}$ C) and O₂ (Scheme 1b).

The reactivity of O_2^{-1} with substituted acetonitriles is affected by the electron-withdrawing and leaving propensities of the substituent group. The more positive the reduction potential of the substituted nitrile, the more facile is nucleophilic displacement by O27. Likewise, the greater the electron-withdrawing by the substituents the smaller the pK_a of the methylenic hydrogens. The results of Table 1 indicate that the reaction rates of halogenonitriles with O_2^{-1} vary according to the leaving-group propensity of halide (Br>Cl>F). On the other hand, the relative reaction rates of other substituted nitriles are in the order of electron-withdrawing propensity of the substituent group (CN>C(O)NH₂>Ph₂CH₂ CN) vis-a-vis the Bronsted basicity of O2-. The slight decrease of the reaction rate of BrCH(Me)CN compared to BrCH₂CN is due to weak electron-donation by the methyl group.

Reactivity of O_2^{-} with Dihalocarbons. Superoxide ion readily reacts with substrates that have dihalide groups in aprotic solvents. Table 3 summarizes the reaction stoichiometries and kinetics for the reaction of O_2^{-} with dihalocarbons, and voltammetric reduction potentials $(E_{p,c})$ for dihalocarbons $[X(CH_2)_nX, n=1-6, X=Br, Cl]$ in DMF. There is a rough correlation between the apparent second order rate constants for the reaction of O_2^{-} with dihalocarbons and the number of methylene in substrates (Figure 3). The apparent pseudo-first order rate constants for the reaction of the voltammetrically generated O_2^{-} with the various substReactivity of Superoxide Ion

Figure 3. Reaction rates of dihalohydrocarbons with O_2^{-1} in relation to their carbon number in DMF. (--), Cl(CH₂)_nCl; (--), Br(CH₂)_nBr.

rates are related to the ratio of i_{ha}/i_{hc} for O_2 in the presence of substrate; the normalized pseudo-first order rate constants are tabulated in Table 3. The apparent reaction rates for O_2^- with the dihalocarbons are determined from cyclic voltammetric peak-current measurements and rotating ring-disk electrode technique. The reaction stoichiometry of superoxide ion per substrate (O_2^-/S) was determined by adding a known amount of substrate to a known excess of O2- in aprotic solvents. The results of Table 3 and Figure 3 indicate that five-membered rings can be rapidly formed by the cyclization of substrate and O2⁻, and the relative rates of cyclization depend on the number of methylenic carbons Br(CH₂)_n Br[n=1<2<3>4>5]. Vicinal dibromoalkanes react with O_2^{-1} to produce products of carbon-carbon bond cleavage.²⁷ The mechanism proposed for these reactions is a nucleophilic attack on carbon followed by a one-electron reduction of the peroxy radical and nucleophilic displacement on the adjacent carbon to form a dioxetane that subsequently cleaves to form two molecules of aldehyde. Therefore, the reaction of O_2^{-1} with Br(CH₂)₂Br as a kind of vicinal dibromo groups yields bromide ion, dioxygen, and two equivalents of formaldehyde. A reasonable mechanism for this cyclization is an initial nucleophilic attack of a bromo carbon by O_2^{-1} as a rate limiting step, followed by displacement of a bromide ion. A second O_2^{-1} reduces the peroxy radical to a peroxide ion, which attacks another bromo carbon to displace the second bromide ion to produce a ring intermediate.

Synthesis of N-Substituted Isoindolin-1-ones via Palladium-Catalyzed Carbonylative Heterocyclization of o-Bromobenzylbromide with Carbon Monoxide and Primary Amines

Sang Chul Shim*, Li Hong Jiang, Dong Yub Lee, and Chan Sik Cho

Department of Industrial Chemistry, College of Engineering, Kyungpook National University, Taegu 702-701, Korea Received July 14, 1995

A convenient method for the synthesis of N-substituted isoindolin-1-ones is disclosed in palladium(0)-catalyzed heterocyclization of o-bromobenzylbromide with carbon monoxide (CO) and primary amines in DMF at 100 \degree .

Introduction

Transition metal-catalyzed carbonylative heterocyclization has been a useful synthetic tool for the formation of a variety of heterocyclic compounds.¹ Thus, the carbonylative cyclization has been effectively applied to the synthesis of isoindolin-1-ones; *i.e.* the cobalt-catalyzed carbonylative cyclization of Schiff's bases with CO,² the carbonylation of *o*-palladated benzaldimines and tertiary benzylic amines,³ the palladiumcatalyzed carbonylative cyclization of *N*-benzyl-*o*-bromobenzylamine with CO,⁴ and the cobalt-catalyzed carbonylative cyclization of *o*-bromobenzylamines with CO under sunlampirradiated phase transfer catalyst (PTC) conditions.⁵ On the other hand, as part of our series of studies on the transition metal-catalyzed heterocyclization,⁶ we have now found that o-bromobenzylbromide reacts with CO and primary amines in DMF in the presence of a catalytic amount of a palladium compound to afford the corresponding isoindolin-1-ones in good yields. The results presented here lead to the one pot procedure for the synthesis of the N-substituted isoindolin-1-ones from three components, o-bromobenzylbromide, primary amines, and CO.

Results and Discussion

Although Mori⁴ and Brunet⁵ partly investigated the transi-
