Hereditary hemorrhagic telagiectasia (HHT), which is characterized by the classic triad of mucocutaneous telangiectases, arteriovenous malformations (AVMs) and inheritance, is an autosomal dominant disorder. The characteristic manifestations of HHT are all due to abnormalities of the vascular structure. This report deals with the case of a 14-year-old girl with typical features of HHT that include recurrent epistaxis, mucocutanous telangiectases, pulmonary and cerebral AVMs and a familial occurrence. **(Korean J Pediatr 2007;50:1018-1023)**

Key Words : Telangiectasia, Hereditary Hemorrhagic, Recurrence, Epistaxis, Arteriovenous Malformations, Inheritance Patterns

Introduction

Hereditary hemorrhagic telagiectasia (HHT), which is also known as Rendu-Osler-Weber disease and is characterized by the classic triad of mucocutaneous telangiectases, AVMs and inheritance, is an autosomal dominant disorder. In recent studies, the incidence of the disease was estimated to be approximately 1 in 5,000-8,000[1-3] and about 20% of patients were estimated to have a negative familial history. Spontaneous recurrent epistaxis, which is caused by bleeding from telangiectases of the nasal mucosa, is the most common manifestation[4]. Telangiectases can occur throughout the gastrointestinal (GI) tract and on the lips, tongue, buccal mucosa, face, ears, hands and fingertips[5, 6]. Pulmonary AVMs occur in approximately 15-20% of patients with HHT[7], and cerebral AVMs occur in 4%[8], while hepatic AVMs rarely occur. Several cases of HHT have been reported in Korea, but there was only two cases in children, which manifested by frequent epistaxis and pulmonary AVMs without cerebral AVMs and a family history of HHT[9]. We describe a case of HHT which is manifested by recurrent epistaxis, AVMs in the lung and brain and a family history of HHT.

Case Report

A 14-year-old girl was referred to our hospital because of recurrent nose bleeds and pulmonary AVMs. She had been suffering from recurrent nose bleeds, which occurred approximately three times a week, since she was six years old. She had also suffered from dyspnea on exertion two years ago, which had been observed without any medical intervention. When she went up a mountain one month prior to our analysis, her dyspnea was aggravated and cyanosis developed, forcing her to visit an outside hospital. The chest radiography and chest computed tomography (CT) were then conducted, which revealed pulmonary AVMs. She was transferred to our hospital for further evaluation and management of the pulmonary AVMs.

On family history (Fig. 1), her grandmother had been receiving a monthly red blood cell transfusion due to recurrent GI bleedings. In addition, her father had been operated on for pulmonary AVMs, had been having recurrent nose bleeds and had been suffering from iron deficiency anemia (IDA), while her brother had been operated on for cerebral AVMs and got quadriplegia as that sequela.

On the day of admission, she had lip cyanosis. Oxygen saturation was approximately 80% in room air. Her conjunctivae were slightly anemic and multiple telangiectases were observed on the tongue (Fig. 2). The chest wall was expanded symmetrically without retraction and breathing sound

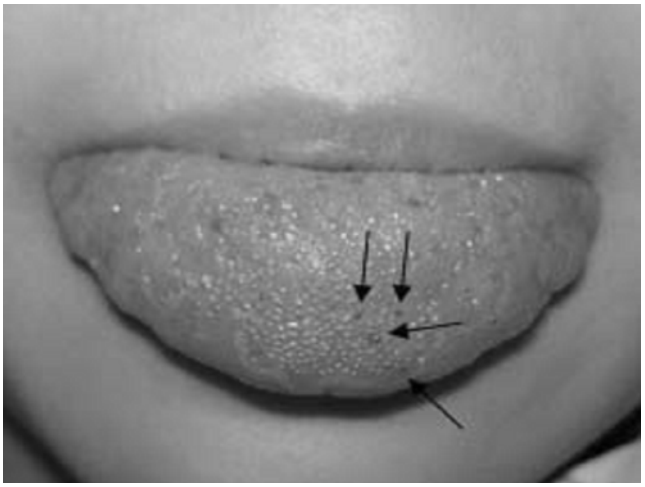

Fig. 2. Multiple telangiectases (arrows) are observed on the tongue.

was clear without rales nor wheezing. Heart sound was regular without audible murmur. Digital clubbing was observed.

Blood laboratory findings demonstrated that IDA such as hemoglobin was 10.6 g/dL, iron was 22 ug/dL, total iron binding capacity was 495 ug/dL and ferritin was <3 ng/mL. The chest radiography showed multiple, round-shaped lesions in the middle and lower lobe of the right lung and lower lobe of the left lung (Fig. 3). The chest CT demonstrated AVMs in both lungs (Fig. 4). There was no pul-

monary hypertension finding in the echocardiography. The pulmonary angiography was performed and coil embolization was done for the large pulmonary AVMs in the middle lobe of the right lung (Fig. 5). Oxygen saturation was increased from 80% to 95% just after coil embolization. Pulmonary AVMs remained in the middle and lower lobe of the right lung and lower lobe of the left lung (Fig. 6), for which coil embolization was to be scheduled. The brain magnetic resonance imaging (MRI), magnetic resonance angiography (MRA) and transfemoral cerebral angiography (TFCA) revealed a cerebral AVM in the left superior frontal gyrus (Fig. 7) and was treated by the gamma knife. The abdomen CT demonstrated no evidence of hepatic AVMs or abnormal AVMs in the abdomen and pelvis. The otolaryngologic examination was performed for recurrent epistaxis and telangiectases were detected in the left nasal cavity. Electrocauterization failed. The TFCA was performed and embolization was done for the telangiectases (septal branch of the left sphenopalatine artery and superior labial artery of the left infraorbital and facial artery). The recurrent spontaneous nose bleeds continued but the frequency and amount of epistaxis were decreased.

Discussion

Hereditary hemorrhagic telangiectsia, or Rendu-Osler-Weber syndrome, is an autosomal dominant disease, characterized by mucocutaneous telangiectases, AVMs and familial occurrence. The diagnosis of HHT is a clinical diagnosis based on the Curaçao criteria[10], which contains the following four main clinical features: (i) spontaneous recurrent nosebleeds; (ii) muco-cutaneous telanigectasia; (iii) visceral AVMs; (iv) an affected first-degree relative. These criteria define "definite HHT" where three criteria are present, "suspected HHT" where two criteria are present or "unlikely HHT" where only one criterion is present. According to these criteria, our patient was diagnosed as having "definite

HHT".

Genetic linkages to HHT have been established to chromosome 9p33-34 in some families[11] and to chromosome 12q in others[12]. It is possible that genes on the other chromosomes may also create the condition[13]. The gene for HHT at chromosome 9p33-34 has been identified as endoglin (ENG)[14]. The gene encoding for HHT at chromosome 12q has been identified as activin-receptor-like kinase 1 (ALK1)[15]. ENG and ALK1 both encode a homodimeric integral membrane glycoprotein, which is the surface receptor for transforming growth factor-β (TGF-β) that is known to have a regulatory role in tissue repair and angiogenesis. It is thought that abnormal vessels in HHT develop because of aberrant TGF signaling at some stage during vascular development and homeostasis[16]. The characteristic manifestations of HHT are all due to vascular structural abnormalities of the nose, skin, lung, brain and GI tract[5]. In this case, the patient's grandmother, father and brother are suspected of HHT and a genetic linkage analysis for this family is needed, which will be helpful for genetic counseling during her pregnancy and for predicting the prognosis of the patient and her family involved in HHT.

Epistaxis caused by spontaneous bleeding from telangiectases of the nasal mucosa is the most frequently noticed symptom of HHT and is found in approximately 90% of the patients[4]. Recurrent epistaxis begins by the age of 10 in many patients and by the age of 21 in most, becoming more severe in later decades of life in about two-thirds of affected individuals[5]. In this case, the patient had also been having recurrent spontaneous nose bleeds since 6 years of age. It had a massive impact on the quality of her life. Embolization was done for the telangiectases in the left nasal cavity. Treatment such as electrocauterization, intranasal topical estrogen and septodermoplasty was used[17, 18] and embolization was not tried yet in Korea. This is the first case treated with embolization for epistaxis caused by telangiectases in Korea.

Mucocutaneous telangiectases occur in about 50-80% of individuals and typically present later in life than epistaxis. The lesions mostly occur in any combination of the face, lips, mouth, tongue and buccal mucosa, ears, hands, fingertips and chest, although they can also occur elsewhere[5, 6]. There may be bleeding from mucocutaneous telangiectases, but it is rarely clinically significant and the main concern is cosmetic. The patient in this case had multiple telangiectases on the tongue, but these were not observed in any other places on her body.

Pulmonary AVMs consist of direct connections between a branch of a pulmonary artery and a pulmonary vein through a thin-walled aneurysm. It is estimated that approximately 60%-70% of persons with pulmonary AVMs have HHT[7]. Conversely, it is estimated that 15-20% of persons with HHT have pulmonary AVMs, but the incidence of these lesions apparently varies according to specific gene mutation for the condition like ENG and ALK1 that is present[19]. Pulmonary AVMs result in direct right-to-left shunts

and bypass the capillary bed. Right-to-left shunts such as these cause hypoxemia, dyspnea, hemoptysis and polycythemia. The right-to-left shunt and absence of a filltering capillary bed allow embolism that can reach the systemic arteries and especially the passage of septic emboli can lead to neurologic complications including transient ischemic attack, cerebral stroke and cerebral abscess[4]. The screening examination for pulmonary AVMs is strictly recommended, since severe complications such as stroke or brain abscess can arise[20]. The helical CT with a contrast agent can be very cost-effective in spite of its adverse effect of radiation exposure. The treatment of pulmonary AVMs includes therapeutic embolization and surgical resection, and these can almost always be treated completely and permanently using embolization[21]. In this case, the patient had cyanosis and dyspnea on exertion and the chest CT was performed, which revealed pulmonary AVMs that were treated by coil embolization.

According to recent studies, the occurrence rate of cerebral AVMs in HHT is approximately 4%[8]. Neurologic symptoms including migraine headache, brain abscess, transient ischemic attack, stroke, seizure and intracerebral and subarachnoid hemorrhage are common in patients with HHT, particularly those with a personal or family history of pulmonary AVMs[4]. For two-thirds of those in whom neurologic symptoms develop, pulmonary AVMs are the source of the symptoms[22]. In the remaining one-third, cerebral or spinal AVMs lead to subarachnoid hemorrhage, seizure, or less commonly, paraparesis[23, 24]. According to a recent study, the risk of being presented with an intracerebral hemorrhage from a cerebral AVM in patients with HHT is approximately 2%[8]. For diagnostic screening purposes, a cerebral MRI is currently the most sensitive non-invasive method, even though it can fail to detect the presence of AVMs. Cerebral AVMs are treated in different ways depending on their size, structure and location in the brain. Neurovascular surgery, embolotherapy and stereotactic radiosurgery can all be used, separately or in combination. The patient in this case did not have neurologic symptoms, but for the purpose of screening, a brain MRI & MRA were performed, which revealed a small AVM in the left superior frontal gyrus, removed by a gamma knife without a sequela. Her brother was operated on for cerebral AVMs and got quadriplegia as that sequela. Her grandmother and father did not have any neurologic symptoms and a brain-imaging study was not conducted on them. Several cases of HHT have been reported in Korea but there was only two cases in children which manifested by pulmonary AVMs without cerebral AVMs and a family history of HHT[9]. In other words, this is the first case of HHT combined with cerebral AVMs and a strong family history in children which has not been reported yet in Korea.

Recurrent hemorrhage of the GI tract occurs in a minority of patients with HHT and is one of the manifestations of the condition that is most difficult to manage[17]. GI bleeding does not usually start until the fifth or sixth decade[5]. Telangiectases occur throughout the GI tract and are more commonly situated in the stomach or duodenum than in the colon. AVMs and aneurysms are less common. Photocoagulation using bipolar electrocoagulation or laser technique may control bleeding GI telangiectases in the short term but are less effective over the long term. In this case, the patient did not have a history of GI bleeding but her grandmother had been having recurrent GI bleeding and had been receiving a monthly red blood cell transfusion.

Liver involvement due to the presence of multiple AVMs or atypical cirrhosis is a rare but important manifestation of HHT. Patients with hepatic involvement of HHT can also have with high-output heart failure, portal hypertension and biliary disease[26]. Hepatic AVMs are currently treated only if a patient shows signs of liver or heart failure as a result of their hepatic AVMs. Embolization, which has been so successful for the treatment of pulmonary AVMs, can cause severe complications when performed in the liver.
