Pesticides have provided significant benefits including plant disease control and increased crop yields since people developed and utilized them. However, pesticide use is associated with many adverse effects, which necessitate precise toxicological tests and risk assessment. Most of these methods are based on animal studies, but considerations of animal welfare and ethics require the development of alternative methods for the evaluation of pesticide toxicity. Although the usage of laboratory animals is inevitable in scientific evaluation and alternative approaches have limitations in the whole coverage, continuous effort is necessary to minimize animal use and to develop reliable alternative tests for pesticide evaluation. This review discusses alternative approaches for pesticide toxicity tests and hazard evaluation that have been used in peer-reviewed reports and could be applied in future studies based on the critical animal research principles of reduction, replacement, and refinement.

Key words: Pesticides, Alternative approach, Toxicological methods, Pesticides evaluation

INTRODUCTION

According to Korean agricultural chemicals regulation law, pesticides include germicides, insecticides, and herbicides used to prevent disease and agricultural pests such as germs, insects, nematodes, mites, viruses and weeds that can damage to agricultural produce (1). Pesticides are essential to control disease and pests to increase food production and improve plant breeds on limited farmland. However, there are sensitive harmful effects from using pesticides. A notable example is pesticide residue. Concern for public health has been raised because of remaining pesticides in foods and environmental contamination is caused by the spraying of agricultural chemicals. Therefore, it is important to test the toxicity of pesticides before and after their

release into the environment.

To assess the impact of pesticides on human health, toxicological classification must to be performed. Most toxicity tests for pesticides determine via oral exposure, application to the skin and the respiratory system. Among these, based on the result of acute oral toxicity test, the potency of toxicity is classified. Acute oral toxicity test is performed with two species of animals and they are administered orally. After 48 hrs, in accordance with median lethal dose (LD₅₀), which causes death in half of exposed test animals, pesticides are categorized as extremely hazardous, highly hazardous, moderately hazardous, or slightly hazardous (2).

In order to calculate LD₅₀ values and test skin irritation, a majority of laboratory animals are employed. At present, people show ethical concerns and severe opposition to traditional toxicity tests. Since the 3R principle – reduction, replacement, and refinement – was proposed by B. Russell and R. Burch in 1959 (3), alternative approaches have been developed based on ethical considerations of animal welfare. Internationally, technical development of *in vitro* tests using cultured cells and *in silico* computer analysis has progressed satisfactorily to allow these tests to be considered as alternatives to *in vivo* tests using laboratory animals.

For instance, since 2009, the European Union has prohib-

ited the production and sale of cosmetics tested on animals. And the European Center for Validation of Alternative Methods (ECVAM) has been established to develop non-animal tests and to assess the reliability and relevance of tests for European regulatory mandates (4). Additional organizations created for developing and validating alternative methods include the Interagency Coordinating Committee for Validation of Alternative Methods (ICCVAM, USA), the Zentralstelle zur Erfassung und Bewertung von Ersatz- und Ergänzungsmethoden zum Tierversuch (ZEBET, Germany), and Korean Center for the Validation of Alternative Methods (KoCVAM, Korea).

In Korea, animal protection law was amended completely in 2007 and the Ministry of Agriculture, Food and Rural Affairs prepared a legal basis for the principles of animal tests and Institutional Animal Care and Use Committee (IACUC). Clause 13 of the animal protection law covers the principles of animal testing based on replacement, reduction, and refinement. Under clause 25, which delineates the constitution of the IACUC, the chief of an institution conducting animal experiments must constitute and operate an IACUC to protect animals and ensure that they are handled ethically. To experiment with animals, study plans must be considered by the IACUC, which can require actions to be taken for the protection of the animals used in the experiments (5). The Rural Development Administration (RDA) of Korea has also amended the 'Standard for Registration of Pesticides', which introduces methods to reduce experimental animal use and shift experiments to artificial cell lines, in accordance with the goal of maximizing animal welfare (6).

In 2010, Korea was the fifth in the world to join the 'International Cooperation on Alternative Test Methods' initiative, which focuses on the validation of alternative testing methods. The alternative tests introduced include acute oral toxicity and skin sensitization tests that use fewer animals than the traditional tests. For example, the traditional acute oral toxicity test uses approximately 50 rats whereas the alternative test can evaluate toxicity using 6-12 rats. The existing skin sensitization test uses a minimum of 30 guinea pigs and takes over a period of 20 days, whereas the alternative test replaces guinea pigs with mice, reduces the number of animals to fewer than 20, and shortens the tests duration to less than 8 days. The RDA concluded that there is little difference in safety between existing test methods and animal alternative tests (7).

Many tests for evaluating the toxicity of pesticides have been performed since agricultural chemicals were developed. This review will discuss materials related to toxicological tests of agricultural chemicals and published studies using alternative methods categorized as *in vitro*, *in vivo* and *in silico*. The endless endeavor of scientists developing alternative toxicity tests suggests a positive outlook for pesticide usage and protection of animals and ecosystems.

CURRENT ISSUES IN TOXICOLOGICAL TESTS FOR PESTICIDES

Residues from pesticides have had negative consequences for humans and the environment since their introduction. Pesticides can be exposed to the manufacturers and farm workers as well as the general population. Non-occupational exposure may occur through the use of improper hazardous pesticides in cities, public parks, golf club, and other environments such as swimming pools, and this exposure has a potential harmful influence on public health. When pesticides contaminate soil, rivers, and oceans, they may be able to produce adverse effects on non-target ecosystems. Therefore, it is urgent to measure pesticide exposure and to evaluate the toxicity level in humans, animals, and the environment.

Among the impacts on the ecosystem, the concern of harmful effect on honeybees has been evoked recently. Since 2007, researchers have increased their efforts to find a cause for the colony collapse disorder (CCD) phenomena which has decimated bee colonies. The issue is very complex, with many potential contributing factors, including parasites, pesticides, and stress. However, pesticides have consistently been implicated as a key issue in pollinator decline, through acute toxicity causing death and through sublethal exposure causing changes in bee reproduction, navigation, and foraging (8). Many scientific inferences have discussed the potential roles that pesticides applied to crops may play in honeybee health. Although no specific pesticide has been clearly associated with CCD, there are some evidences for the additive and synergistic effects of multiple pesticides on harming bees (9). Despite the importance of honeybees, the effects of pesticide exposure on colony health have not been systematically monitored, and the US Environmental Protection Agency (EPA) does not require data on sublethal effects for pesticide registration. The use of newer systemic pesticides, including neonicotinoids and phenylpyrazoles has become prevalent in the USA and these compounds are also present in plant tissues. Honeybees' exposure to these compounds is very different from that of traditional pesticides, where acute toxicity is a primary concern. Instead, honeybees at all stages of development may be chronically exposed to sublethal doses of these compounds. Restricting the use of new compounds may result in a reversion to older chemistries that are known to harm bees (9). Studies concerned with the potential impact of pesticides on beneficial organisms, including bees, are needed to influence the effective policymaking that ensures the long-term survival of the species and its economic impact.

Former pesticide toxicity testing methods required the use of large numbers of laboratory animals for LD₅₀ calculation. Therefore, new methods have been developed that drastically reduce the number of animals compared to traditional methods. Two representative examples are the new

acute oral toxicity test guidelines in the OECD *Guidelines* for the Testing of Chemicals, Test Guideline 420 and Test Guideline 423.

Test Guideline 420 is a refined approach to acute toxicity testing that was suggested by the British Toxicology Society in 1984 based on the administration of compounds at a series of fixed dose levels. The statistical properties of the Fixed Dose Procedure have been evaluated using mathematical models in a series of studies. In this procedure, groups of animals of a single sex are dosed in a stepwise procedure using the fixed doses of 5, 50, 300 and 2000 mg/kg. The initial dose level is selected as the dose expected to produce some signs of toxicity without causing severe toxic effects or mortality on the basis of a sighting study. Clinical signs and conditions associated with pain, suffering, and impending death, are described in detail in a separate OECD guidance document. This procedure continues until the dose causing evident toxicity or no more than one death is identified, when no effects are seen at the highest dose or when deaths occur at the lowest dose (10).

Test Guideline 423 is an acute stepwise toxicity testing procedure that uses 3 animals of a single sex per step. Depending on the mortality and/or the moribund status of the animals, 2~4 steps are usually necessary for evaluating the acute toxicity of the test substance. The method, as adopted in 1996, was extensively validated *in vivo* against LD₅₀ data obtained from the literature, both nationally and internationally (11). These procedures are reproducible, use very few animals, and are able to rank.

New methods of testing the toxicity of agricultural chemicals are quicker and cost less than previous method. Experimental comparison between existing methods and new alternative methods will allow for toxicological classification of pesticides with respect to economic considerations and animal welfare concerns. Because pesticides are extensively utilized, policy decisions regarding, regulation and risk assessment are very important. Pesticide-related laws, management programs, and institutions have supported the development and experimenting of alternative testing methods around the world. Adherence to good laboratory practices (GLPs) provided in OECD guidelines minimizes overlapping experiments by facilitating the sharing of experimental results and laboratory techniques. Developed countries that are party to the OECD require experimental results obtained by GLP test agencies as toxicity test reports for all pesticides. In Korea, the RDA manages GLP system related to toxicity test of pesticides. Methods of pesticides testing are performed according to the standards and methods of registration of pesticides notified by the RDA, and foreign test standards such as those of the OECD and US EPA can also be accepted interchangeably (12).

Many nations have enacted and amended laws regulating agrochemicals. In Korea, agricultural chemicals regulation law was enacted and promulgated in 1957 and recently

amended in 2014 to improve environmental conservation and public health by setting regulations regarding the manufacturing, import, safe usage, and handling of pesticides (1). In the European Union (EU), legislation on pesticides is found in regulation EU regulation 283 and 284, which sets safety data requirements for active substances and plant protection products (13). In the United States, registration, regulation, and risk assessment of pesticides follow guidelines in the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) that are enforced by the U.S. EPA (14).

For the improved protection of human health and the environment, the U.S. EPA is developing and evaluating new molecular, cellular, and computational methods to supplement or replace more traditional methods of toxicity testing and risk assessment. The EPA's Pesticide Program prospect the results in computer-aided methods for better prediction of potential hazards and exposure amount, minimization of the number of animals, improved understanding of toxicity pathways, and search for diagnostic biomonitoring and surveillance methods to detect chemical exposures (15).

Furthermore, international harmonization of test guidelines by the OECD for chemicals/pesticides and the veterinary medicine, International Conference on Harmonization (ICH and VICH) have contributed in minimizing duplicate testing, probably save more animals than any single alternative method. International harmonization is as important as economic harmonization (16).

IN VITRO ALTERNATIVE PESTICIDE TOXICITY TESTING METHODS

In vitro (meaning "in glass" in Latin) study is experimentation with samples of tissue or cells under artificial conditions and outside of living organisms. *In vitro* testing procedures are important alternative agrochemical toxicity testing methods that meet the criteria of reduction, replacement, and refinement. Furthermore, *in vitro* tests offer several advantages over traditional *in vivo* methods, including controlled testing conditions, a high level of standardization, a reduction in variability between experiments, the absence of systemic effects, low cost, a small amount of required material, a limited amount of toxic waste, and reduced need for animals (17).

Each fields of toxicity studies have developed and used for investigation of agrochemicals. Several assays are used to predict pesticide-induced immunotoxic effects. The effects of persistent exposure to pesticide chemicals on the integrity of the immune system have recently drawn considerable interest as an additional indicator of potential problems. Pistl *et al.* (18) aimed to determine the action of several pesticides of different chemical structures with regard to biological effects on the function of phagocytes and lymphocytes isolated from the peripheral blood of

sheep under *in vitro* conditions by using the iodo-nitro-tetrazolium reductase test and the leukocyte migration-inhibition assay. Assays for immunotoxicity must consider studies on humoral, cell-mediated immunity, leukocytes and nonspecific immunity.

Some widely used agrochemicals are suspected to disrupt hormonal homeostasis, and thus adverse effect of pesticides on reproductive and endocrine systems should be studied. Anderson *et al.* (19) tested 24 pesticides *in vitro* for interactions with the estrogen receptor (ER) and the androgen receptor (AR) in transactivation assays. Estrogen-like effects on MCF-7 cell proliferation and effects on CYP19 aromatase activity in human placental microsomes were detected. Estrogenic properties of test compounds could be estimated by measuring mRNA levels of ER α and ER β (20). *In vitro* reporter gene assays using Chinese hamster ovary cells and inhibition of CYP19 aromatase activity seemed to be powerful screening tools for reproductive disruption by many pesticides (21).

Selected different classes of pesticides have been reported to have genotoxicity and mutagenicity. Thus, investigators have designed *in vitro* tests for these effects. The *in vitro* sister chromatid exchange (SCE) assay in human lymphocytes was suggested as a sensitive method of measuring the potential mutagenicity/carcinogenicity of pesticides (22). DNA damages by pesticides also could be estimated by measuring chromosomal aberrations (chromatid breaks, fragments, gaps, aneuploidy, and satellite association) and standard alkaline comet assay on human peripheral lymphocytes *in vitro*. The experimental results suggested that analysis of genotoxicity may serve as an important indicator of the risks of occupational and household exposure to pesticides (23-25). Due to the complex metabolic competence, the chicken embryo may serve as a standard model system for genotoxicity testing, owing to its capability of undergoing metabolic activation and deactivation of xenobiotics. The micronucleus test and the comet assay using the chicken embryo can be performed to evaluate the genotoxic potential of insecticides (26,27).

Some pesticides are hematotoxic and cause agranulocytosis, neutropenia, thrombopenia and anemia. Parent-Massin and Thouvenot (28) had performed pesticide hematotoxicity, using human and rat progenitor cells, human and rat colony-forming unit-granulocyte and macrophage (CFU-GM), known to be either hematotoxic or innocuous for blood cells. Their results demonstrated that pesticides known to be hematotoxic *in vivo* inhibited the development of progenitors *in vitro*. Such techniques, therefore, could be used in predictive and retrospective studies to identify chemicals responsible for hematotoxicity.

Many classes of insecticides, such as organophosphates and carbamates, have neurotoxic potential. Therefore, alternative neurotoxicity tests are essential for risk assessment of such insecticides. Many researchers have determined the

inhibitory power (I_{50}) of a number of compounds against acetylcholine esterase and neurotoxic esterase - inhibition of which is known to cause neurotoxicity - of hen and human brain *in vitro*. Comparison of the ratio of these I_{50} 's with previous *in vivo* toxicity data suggested that this ratio has predictive value for sensitivity to insecticides (29). Cell cultures derived from nervous system tissue have proven to be powerful tools for elucidating cellular and molecular mechanisms of nervous system development and function, and have been used to understand the mechanism of action of neurotoxic chemicals. Recently, it has been suggested that *in vitro* models could be used to screen for chemical effects on critical cellular events during neurodevelopment, including differentiation and neurite growth. Reports in the literature describe cell culture systems that are used to quantify the effects of pesticides on neurodevelopmental processes *in vitro* by examining their effects on neurite outgrowth (30).

As an alternative to the standard Draize eye irritancy test, the potential irritancy of compounds can be evaluated by observing adverse changes that occur in the chorioallantoic membrane (CAM) of the hen egg after exposure to pesticides. A good correlation was found between this CAM assay and the *in vivo* Draize eye irritation test (31). Thus, it could be a valid predictor of irritation and/or corrosion induced by pesticides in human eyes. This assay represents an *in vitro* alternative method that is expected to reduce public concerns, required experimenter's time, and use of rabbits for pesticide assessment.

Artificial human three-dimensional skin models have gradually replaced *in vivo* skin irritation and sensitization tests in recent years. In particular, toxicologists are applying such models to toxicity tests for cosmetics. A three-dimensional human skin model consisting of several layers of actively dividing and metabolically active human neonatal foreskin-derived fibroblasts and epidermal keratinocytes grown on nylon mesh has been used to assess the *in vitro* toxicity of pesticides (32). Nowadays, few companies construct and sell human skin models such as KeraSkinTM, EpiSkinTM, and MelaSkinTM. Thus, many investigators are using these models for pesticide testing. Jeong *et al.* (33) studies the effects of several pesticides on KeraSkinTM and measured the cell viability in the culture medium collected after treatment with pesticides for 24~72 hrs. Changes in cell viability caused by the formulation were taken as predictors of skin irritation and results suggested that alternative testing methods using the KeraSkinTM model could be used to evaluate pesticide toxicity equivalent to a primary irritation index (P.I.I.) score of greater than or equal to 2.1. Further studies of pesticide skin irritation using alternative methods are necessary to validate these improved methods of alternative pesticide safety evaluation (33). As for cosmetics industry, it is anticipated that artificial 3D skin models may entirely replace animal skin testing in pesticide industry for

release and permission of new products, mechanism studies and risk assessment.

Recently, a neutral red uptake (NRU) assay with epithelioma papulosum cyprini (EPC) cell was developed as an alternative to the fish acute toxicity test. The epithelioma papulosum cyprini (EPC) cell is originated from the epidermal tissue of *Cyprinus carpio* (common carp). Results from *in vivo* fish acute toxicity tests conducted according to OECD Test Guideline No. 203 using *Aphyocypris chinensis*, *Oryzias latipes*, and *C. carpio*, suggested that the EPC cell viability assay represents a viable alternative to the fish acute toxicity test, owing to the good correlation between these tests and the NRU assay is expected to serve as a useful tool for the prediction of acute fish lethality for pesticides (34). However, further studies with a larger set of pesticides are needed to strengthen the reliability of the assays and to validate the correlation with *in vivo* data (34).

IN VIVO ALTERNATIVE PESTICIDE TOXICITY TESTING METHODS

Alternative toxicity testing methods using living organisms indicate the replacement of animals such as vertebrates with animals that are lower on the phylogenetic scale, modifications of husbandry or experimental procedures to enhance animal well-being and minimize or eliminate pain and distress and the use of fewer animals. The 'Guide for the Care and Use of Laboratory Animals' plays an important role in decision making regarding the use of vertebrate laboratory animals because it establishes the minimum ethical, practice, and care standards for researchers and their institutions (35).

As animal-replacing methods, fishes, amphibians such as the tadpole, or invertebrates such as the sea urchin could be taken advantage of pesticides toxicity testing. They have lots of advantages. That is to say, these animals can be applied in various conditions, bred and manipulated easily, and are available in many different species and sizes. Also, they can be used in various field of pesticide toxicity such as embryology, neurobiology, endocrinology, and carcinogenesis. Rudek *et al.* (36) demonstrated that pyrethroid causes mitotic spindle damage, clastogenic activity and micronucleated red blood cells using tadpoles (*Rana temporaria* and *Xenopus laevis*). The micronucleus test in amphibians represents an excellent tool for alternative testing and monitoring of pesticide toxicity in natural water.

The fish embryo toxicity (FET) test has been proposed as an alternative to the acute fish test. It can be used to collect data on various types of environmental assessments (e.g., hazard, risk, effluent, and classification and labeling of chemicals). The establishment of definitive testing strategies and procedures for a fish eleutheroembryo toxicity (FEET) test is in progress and will provide another option for acute test-

ing of juvenile or adult fish (as in OECD 203 and similar guidelines) in the near future (37).

Invertebrates usually raise less societal concern than mammals, birds, or even lower vertebrates such as fish. Invertebrate species seem to be useful animal models to link, in a mechanistic way, suborganismal effects of environmental chemicals to changes at the population and community levels. Thus, replacement of vertebrates with invertebrates in ecotoxicity testing of pesticides is quite feasible. In laboratory tests or field studies, the actual or potential value of invertebrates as alternatives is evaluated from their ability to replace or prevent the use of vertebrates. For example, the study of the mechanism of action of pyrethroid was performed using various experimental models, including squid giant axon, crayfish giant axon and stretch receptor organ, snail neurons, cockroach nerve cord and giant axon, and isolated insect neurons (38). Some insecticides and herbicides were investigated using an embryogenesis bioassay in the sea urchin and other marine invertebrates, and it was demonstrated that the procedure toxicity testing on non-target marine species and for the assessment of the biological quality of marine water (39).

However, the most important problem facing species replacement is that of extrapolation of responses to environmental chemicals from invertebrates to vertebrates (including humans), which is very difficult because of the differences in pharmacokinetics, pharmacodynamics, detoxification, recovery and other factors (38). Such translation issues severely inhibit the prompt adoption of alternative testing methods and should be a focus of research in the near future.

As an example of subject reduction, OECD recommends that laboratory animal usage could be reduced by using cytotoxicity tests to estimate starting doses for acute oral systemic toxicity tests because IC_{50} values from *in vitro* basal cytotoxicity tests could be used to predict LD_{50} values for use as starting doses for the Acute Toxic Class (ATC) method (TG 423) or the Up-and-Down Procedure (UDP) (TG 425) test guideline. Simulations for reference substances showed that using *in vitro* cytotoxicity assays to estimate an LD_{50} to use as a starting dose could reduce animal use by up to 28% for acute oral toxicity testing, and by as much as 50% for non-classified substances (40).

To predict skin toxicity, such as skin allergic reactions, or contact dermatitis, the murine local lymph node assay (LLNA) can be used based on the protocol of the ICCVAM or the OECD. The ICCVAM recommended the LLNA as a valid alternative to traditionally accepted guinea pig test methods for assessing the hazard potential in most testing situations. The National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) LLNA database of more than 600 substances includes data for 104 pesticide formulations. ICCVAM concludes that these data support the usefulness of the LLNA for testing pesticide formulations (41).

IN SILICO ALTERNATIVE PESTICIDE TOXICITY TESTING METHODS

It is necessary to think creatively to break from conventional animal testing methods. A typical example is virtual environment modeling of organisms. *In silico* is a term created by appearance and advance in bioinformatics. It means technics that study biological phenomena and design drugs using computer simulations (42). As a result of advances in computer technology, nowadays numerous biological reactions can be modeled and predicted with high class-algorithm. The advantages of *in silico* tools are low cost,

standardization, minimal equipment needs, minimal training requirements, and fast execution. In general, *in silico* tools allow for advanced biometry and have clearly defined usage scopes (16).

A strong promoter of *in silico* approaches was the Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) legislation passed by the EU (16). Currently, some countries, under support of government, have promoted *in silico* projects based on massive databases and preceding *in vitro*, *in vivo* experiments. In case of the United States, the EPA launched a related program called ToxCast in 2007 which aims to screen and prioritize chemi-

Table 1. Summary of current state on alternative pesticide toxicity testing areas in this review

<i>In silico</i>	ToxCast program (USA) (43) Establishment of Center for cost-effective cell-based and computational toxicity evaluation systems (Korea) (44) Developing a toxicity evaluation system using virtual cells (Japan) (44) Functional genomics (45,46) Structural genomics (45) Structure-activity relationship analysis	Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) legislation (16)

cals for potential human toxicity using *in vitro* assays and *in silico* approaches. The first phase of ToxCast tested 309 active chemicals (mostly pesticide) in 467 assays across 9 technologies, including high-throughput cell-free and cell-based assays, in multiple human primary cells and cell lines. ToxCast has evaluated over 2,000 chemicals and they were evaluated in over 700 high-throughput assays that covered a range of high-level cellular responses and approximately 300 signaling pathways. The large ToxCast data set, which links *in vitro* and *in vivo* assay, results to genes and pathways, providing a unique public resource for researchers modeling chemical biology and toxicity. ToxCast expects to continue to provide innovative computational methods for evaluating potential health impacts of environmental chemicals (43).

In Korea, the National Institute of Food and Drug Safety Evaluation in the Ministry of Food and Drug Safety (MFDS) constituted a center for cost-effective cell-based and computational toxicity evaluation systems in 2010, which is developing eco-friendly technologies to evaluate and predict toxic responses in cells or tissues using molecular biology. More than 150 million laboratory mice are used per year for toxicity testing in Korea. The adoption of *in silico* toxicity evaluation methods is expected by the MFDS to reduce the use of laboratory animals to less than half of its current rate. This change corresponds with a global trend to downscale animal use in toxicological studies for reasons of ethics and high cost. The center has developed molecular screening technology, *in silico* methods of toxicity prediction, and biomarkers of target organ toxicity. In addition, a research institute that is part of the Ministry of Health, Labour and Welfare (MHLW) of Japan, has developed a toxicity evaluation system using virtual cells (44).

Although machines cannot perfectly represent living of laboratory animals, computer models could prevent the unnecessary use of millions of animals in painful toxicity tests. Furthermore, *in silico* methods could be valuable as alternative test for screening the potential risk of many pesticides to public health.

POSSIBLE METHODS WIDELY APPLICABLE TO ALTERNATIVE TESTING OF PESTICIDES

With an advances in modern science like as biotechnology and “-omics” (genomics, proteomics, etc.), numerous alternative approaches have been investigated and established. There are some beneficial and applicable tools that are expected to be utilized widely in agrochemical evaluation.

Functional genomics represents a new phase of genome analysis. It provides a fertile ground for creative thinking to develop innovative technologies that make use of the vast repository of structural genomics information. Specifically, functional genomics refers to the development and application of global (genome-wide or system-wide) experimental

approaches to assess gene function by making use of the information and reagents provided by structural genomics (45). It is characterized by high throughput or large scale experimental methodologies that are combined with statistical and computational analysis of the results. Computational biology performs a critical and expanding role in this area, and functional genomics is characterized by mining of data sets for particularly valuable information. It promises to rapidly narrow the gap between the understanding of sequence and function and to yield new insights into the behavior of biological systems (45). One of good example on pesticide toxicity is functional genomics of the human paraoxonase polymorphisms that levels and genetic variability of the PON1 position 192 isoforms (Gln/Arg) influence sensitivity to specific insecticides or nerve agents (46). More investigation in this area is definitely needed to be pursued.

High-throughput *in vitro* toxicity screening (HTS) was initially developed by the pharmaceutical industry (47). HTS can provide an efficient way to identify potential biological targets for chemicals. The combination of rapid *in vitro* assays would allow for more efficient risk assessment for a single compound and the accrual of generic information on chemical characteristics for pathway activation to allow for the prediction of the effects (48). The transition to a new toxicity testing paradigm that relies heavily on *in vitro* HTS assays will require a parallel investment to characterize the pharmacokinetics and exposure levels of these chemicals. These parallel efforts will add valuable information on parameters critical to interpreting the biologically relevant exposure scenarios that should yield more informative and effective prioritization models (49).

The concept of evidence-based medicine (EBM) has emerged from clinical medicine, which retrospectively assesses the evidence of adequacy of a given approach. EBM advocates have developed procedures, including meta-analysis, to collect and evaluate all the available evidence in case where definitive studies are unavailable (50). To answer questions about general and specific causation, Guzelian et al. (51) have constructed a framework for evidence-based toxicology (EBT) that is derived from the accepted principles of EBM, and have suggested new toxicological approaches. We customarily distinguish between known relationships (facts) and those propositions that are only possible or partially known (suppositions). EBT represents an objective, systematic method for classifying these relationships as potential or established, based on accumulated knowledge. EBT provides a uniform, structured guide for evaluating quantitative and judgmental aspects of the elements of a causal analysis (51). EBT promises to allow for informed decision making in risk assessment for individual compounds for which several studies are available. For this purpose, the quality score concept for toxicological studies needs to be further developed.

Physiologically-based pharmacokinetic (PBPK) model-

ing refers to the development of quantitative descriptions of the absorption, distribution, metabolism and elimination of chemicals, on the basis of interrelationships among the critical determinants of these processes. PBPK models predict the time-course of parent chemical, metabolite(s) or biomarkers in the exposed organism (52). Some organophosphates have been investigated using PBPK methods. The PBPK model, developed for chlorpyrifos and diazinon, was capable of quantifying target tissue dosimetry and dynamic responses in rats and humans and, thus, could be used to link metabolism to cholinesterase inhibition across species. Furthermore, it could be used to quantitatively assess the risk associated with exposure, as well as to design and focus of future experimental research (53,54). An advantage of PBPK models is that they can be adapted to newer insights, and the knowledge gained from the modeled processes and structures can be expected to increase the model's predictive and explanatory value (55). PBPK models provide a theoretical basis for integrating *in vitro* data and making tissue dosimetry predictions in the animal, thus, allowing for the reduction or refinement of animal use in pharmacokinetic and toxicity studies. PBPK models of other pesticides are urgently needed to facilitate the reduction of animal use.

Sharma *et al.* (56) suggested the use of microfabricated platforms that the disciplines of microscale engineering in conjugation with tissue engineering could potentially provide such a platform and revolutionize the *in vitro* allergy test field. There are several advantages in utilizing microdevices for cell culture. Scaling down to the micron level permits material saving and evaluating responses at a single cell level. Microdevices can simulate interconnected cells found *in vivo* and microfluidics can reproduce *in vivo* like channel sizes. Thus, this type of model provides further methods for alternative toxicity testing and presumed predictability (56).

In addition to the methods described herein, there are other alternative toxicity testing tools that deserve consideration, such as structure-activity relationship analysis, biomarkers, and so on. Because of the limitation of each alternative approaches, to obtain the most precise and valid results, we recommend that several complementary methods had better be used. Greater reliance on these alternative techniques for pesticide testing will reduce the need for animals, assuage ethical concerns, and, then, positively energize pesticide toxicology.

CONCLUSIONS AND EXPECTED FUTURE OF PESTICIDE TOXICOLOGY

Twenty-one century is the era of agriculture and environment. Among these, the beneficial potential of pesticides makes their use inevitable. Therefore, effective testing of the toxicity of agrochemicals is needed to support the development of low-toxicity pesticides. However, animal testing

is costly and engenders ethical concerns. Therefore, it is important to develop non-animal toxicological methods for pesticides that allow for the collection of critical safety data through alternative approaches.

Many issues with alternative toxicity test for agrochemicals remain to be resolved, primarily with regard to some potential limitations and validation of the alternative methodology. Furthermore, extrapolation from dose and exposure of pesticides on cells or animals to real dose and exposure of pesticides on humans or ecosystem could be complicated (4). Thus, it is necessary to secure the validation and overcome the limitations of pesticides alternative toxicity tests. Regulatory agencies and the users of alternative test systems need a process to ensure that "me-too" test kits developed according to the generic descriptions produce results similar to those obtained using the system originally validated and accepted (4). Continued refinement of the *in vitro* assays to better reflect *in vivo* adverse effects and improvement of *in vitro* pharmacokinetic assays will eventually allow researchers to move beyond hazard-based prioritization to risk assessment (49).

Experts-in-these fields estimate that the replacement of animal experiments for most aspects of skin sensitization and toxicokinetics will be possible within 5~9 years, and that within 10 years, this replacement will be required in other areas (17). Although laboratory animals are indispensable in many scientific fields, it is very important that persistent efforts should be focused to minimize animal use, and to apply alternative testing methods in pesticide safety evaluation that also reduce study time and cost.

Pesticide toxicology will benefit greatly from the use of the robust validated alternative methods described herein and the development of novel techniques. If reliable alternative methods for pesticide toxicity evaluation are established and they reflect toxic pathway by actual exposure of each agrochemicals, we could not only satisfy 3R principles and humanity for animals weaker than human but also protect/improve public health and ecosystem. Ultimately, an integrated viewpoint encompassing circumstances of humans, veterinary animals and the environment will advance alternative pesticide toxicology area.
