Dietary manipulation: a sustainable way to mitigate methane emissions from ruminants

Md Najmul Haque

Abstract

Methane emission from the enteric fermentation of ruminant livestock is a main source of greenhouse gas (GHG) emission and a major concern for global warming. Methane emission is also associated with dietary energy loss; hence, reduce feed efficiency. Due to the negative environmental impacts, methane mitigation has come forward in last few decades. To date numerous efforts were made in order to reduce methane emission from ruminants. No table mitigation approaches are rumen manipulation, alteration of rumen fermentation, modification of rumen microbial biodiversity by different means and rarely by animal manipulations. However, a comprehensive exploration for a sustainable methane mitigation approach is still lacking. Dietary modification is directly linked to changes in the rumen fermentation pattern and types of end products. Studies showed that changing fermentation pattern is one of the most effective ways of methane abatement. Desirable dietary changes provide two fold benefits i.e. improve production and reduce GHG emissions. Therefore, the aim of this review is to discuss biology of methane emission from ruminants and its mitigation through dietary manipulation.

Keywords: Diet, Starch, Sugar, Fibres, Greenhouse gas

Background

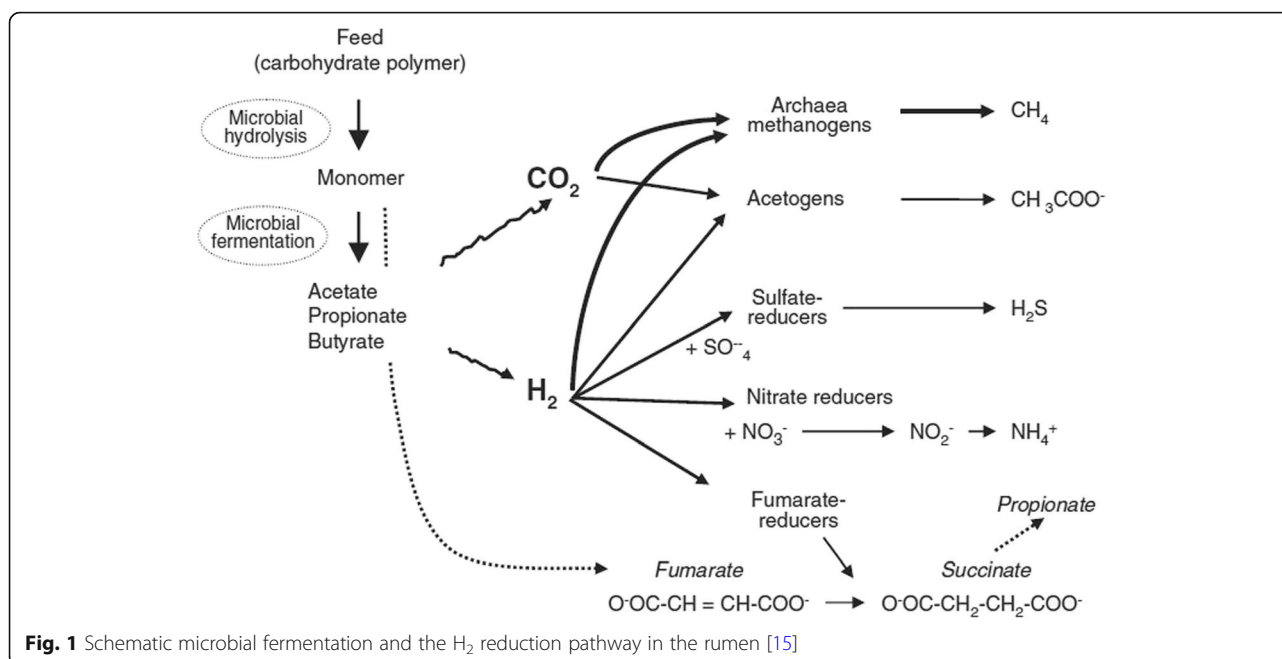

Livestock contribute to global climate change by emitting GHG either directly (from enteric fermentation and manure management) or indirectly (from feed production and the processing and converting of forest into pasture). The major GHGs from the livestock sector are carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O) throughout the production process (Fig. 1.1). The CO₂ that is emitted from livestock is not considered a net contributor to climate change because the animals consume plants that use CO₂ during photosynthesis (Steinfeld et al., 2006). Consequently, CH₄ and N₂O are the most important GHGs from the animal production system and have very high global warming potentials (GWP) of 25 and 298 CO₂ equivalent (eq), respectively [1]. The first comprehensive analysis of the environmental impact of livestock production [2] reported that approximately 18% of the global anthropogenic GHG is contributed by livestock production. The global anthropogenic GHG emissions from agriculture

were 5.1 to 6.1 Gigatonnes CO₂-eq in 2005, of which livestock shared approximately 9% [3]. Within livestock, ruminant supply chains are the main contributors to the GHG, estimating approximately 80% of the total sector's emissions [4], while non-ruminants, e.g., pigs and poultry, contribute only approximately 9 and 8%, respectively, to the sector's emissions [5]. The emissions from beef and milk production represent 35 and 30% of the livestock sector emissions, globally. Buffalos and small ruminant supply chains have a much lower contribution, representing 8.7 and 6.7% of sector emissions, respectively [4]. Another report [5] that stated GHG emissions along livestock supply chains estimated approximately 14.5% of all human-induced emissions. Enteric fermentation and feed production related activities in ruminant production are the primary sources of GHG emissions, representing approximately 39 and 45% of the GHG of the total sector's emissions. The largest source of GHG emissions from ruminant production, i.e., CH₄ derive from enteric fermentation, which accounts for approximately 47%, greater than 90% of the total CH₄ emissions [4]. According to the US Environmental Protection Agency in 2009, CH₄ emissions

from enteric fermentation represented approximately 20% of total CH₄ emissions from anthropogenic sources [6]. The rate of emission in terms of carbon footprint at the product levels is 2.8, 3.4 and 6.5 kg CO₂-eq/kg FPCM for milk production from dairy cattle, buffalo and small ruminants, respectively. However, with regard to meat from ruminants, the carbon footprint for beef, buffalo meat and small ruminant meat is 46.2, 53.4 and 23.8 kg CO₂-eq/kg meat, respectively [4]. According to the values that were projected by EPA [7], the direct non-CO₂ emissions from livestock would be approximately 7.3 to 7.5% of the global GHG emissions between 2010 and 2020, respectively. Ruminant production faces difficult challenges and must reduce GHG emission while responding to the significant demand of livestock products (projected + 70% by 2050 for a world-projected population of 9.6 billion) [5]. The global food demand will also increase with the rapidly increasing global population. Consequently, the demand for animal products will also increase. Therefore, the environmental impact per unit of animal products will obviously be increased. Thus, the sector will be vulnerable in terms of environmental sustainability. Therefore, sustainable and immediate mitigation strategies are in high demand. This review will focus on CH₄ mitigation from ruminants through dietary manipulation.

Methanogenesis and methane production in the rumen

Methanogenesis is a process of CH₄ production in the rumen where H₂ reduced the CO₂ with the help of methanogenic archaea. This is a dynamic process, in which methanogens strongly influence the metabolism of fermentative and acetogenic bacteria via interspecies

hydrogen transfer [8]. The carbohydrate fraction of the feed constitutes structural plant fibre that has been degraded by a consortium of rumen microbes under anaerobic conditions with the production of volatile fatty acids (VFA), CO₂ and H₂ (summarised in Table). During fermentation, hydrogen (H₂) is released into the rumen via the re-oxidation of the reduced cofactors (NADH, NADPH and FADH). The produced H₂ and CO₂ are the major substrates that are used by methanogens, which is considered being the predominant pathway of CH₄ production in the rumen [9]. Methane production from H₂ and CO₂ reduces the partial pressure of H₂, thereby favouring continued fermentation [9]. Without the removal of H₂, the further re-oxidation of reduced cofactors (NADH, NADPH and FADH) would be inhibited by the accumulation of H₂, consequently inhibiting the production of VFA (Table 1) [10].

In addition, the functional group of methanogens also uses formate, acetate, methanol, methylamines (mono-, di- and trimethylamine) and alcohol [9] as presented in Fig. 1. Formate is used by many of hydrogenotrophic rumen methanogens as an alternative to H₂ [11], accounting for up to 18% of the total CH₄ production in the rumen [12]. Acetate is highly available in the rumen environment, but acetoclastic methanogenesis bears very limited importance in the rumen system [13] because the acetate-utilising methanogen *Methanosarcinales* has a very low growth rate and is consequently flushed from the ruminants digestive system [14]. Furthermore, acetogens have a lower affinity to H₂ [15]. Other substrates, including methylamine and methanol, have been investigated for CH₄ production in the rumen. The methyl

Table 1 Volatile fatty acids production (VFA) and reductive process in the rumen adopted from [95, 96]

Substrate		Products	ΔG (KJ) ¹	Reactions
VFA production				
$C_6H_{12}O_6 + 2H_2O$	→	$2 C_2H_4O_2 + 2 CO_2 + 8H^+$		Acetate production

$C_6H_{12}O_6$	→	$C_4H_8O_4 + 2 CO_2 + 4H^+$		Butyrate production
Reductive process				
$CO_2 + 4H_2$	→	$CH_4 + 2 H_2O$	− 67.4	Methane production
$2 CO_2 + 4H_2$	→	$C_2H_4O_2 + 2 H_2O$	− 8.8	Reductive acetogenesis
$SO_4^{2-} + 4H_2 + H^+$	→	$HS^- + 4 H_2O$	− 84.4	Sulfate reduction
$NO_3^- + 4H_2 + 2H^+$	→	$NH_4 + 3 H_2O$	− 371	Nitrate reduction

¹under following rumen conditions: $H_2 = 162$ pa; pH = 6.5; $[H_2O] = 50$ M; $[succinate^{2-}] = 4 \times 10^{-6}$ M; $[malate^{2-}] = [\beta\text{-hydroxybutyryl-CoA}] = [butyryl-CoA] = 10^{-6}$ M; $[acetate^-] = 70$ mM; $[propionate^-] = 25$ mM; $[butyrate^-] = 15$ mM; $[lactate^-] = 1$ mM; $[NH_4^+] = 11$ mM (20 mg/dL); $[HS^-] = 0.14$ mM. ΔG = free energy change indicates how energetically favourable it is i.e. the higher ΔG , the more energy utilization and negative ΔG indicates the energy release

group is rapid converted by the rumen microorganisms to trimethylamine via di- and monomethylamine and is possibly used for CH_4 production [16]. However, only *Methylophilic* methanogens within the order *Methanospiraera* spp. use methanol for CH_4 production [13].

Because neither of these microbes are abundant in the rumen [17], the contribution of these substrates to total CH_4 production is expected to be lower [15]. Consequently, the most favourable CH_4 production pathway in ruminants is the product of H_2 oxidation using CO_2 as an external electron acceptor [9].

Methane mitigation strategies

Methane is expected to contribute approximately 18% of the total expected global warming within the next 50 years [18], of which the contribution of livestock to the total global emission is approximately 9% [3]. Domestic animals account approximately 94% of the total global emissions of animals [18]. Although emissions have decreased per unit of animal product, the total emission has increased from a vast animal population around the globe [4]. By 2050, the total CH_4 emission from ruminant livestock is expected to increase significantly due to the growing demand of milk and meat for a rapidly growing world population [5]. Therefore, it is of utmost importance to mitigate CH_4 emission from the livestock industry. There are several strategies for CH_4 mitigation from ruminants that have recently been reviewed [19–21].

Dietary manipulation

Among the nutritional strategies of CH_4 mitigation, dietary manipulation is a simplistic and pragmatic approach that can ensure better animal productivity as well as a lower CH_4 emission. The schematic diagram of dietary manipulation, which alters the pathway of fermentation to reduce CH_4 , is summarised in Fig. 2.

Dietary manipulation can reduce CH_4 emission up to 40% depending the degree of change and the nature of the

intervention [22]. Another study also indicated that CH_4 emissions can possibly be reduced up to 75% through better nutrition [23]. However, dietary manipulation is the most commonly practiced approach. Dietary strategies can be divided into two main categories: i) improving the forage quality and changing the proportion of the diet and ii) dietary supplementation of feed additives that either directly inhibit methanogens or altering the metabolic pathways leading to a reduction of the substrate for methanogenesis.

Forage

Forage quality has influences CH_4 production in the rumen [24]. High-quality forage, e.g., young plants, can reduce CH_4 production by altering the fermentation pathway because this forage contains higher amounts of easily fermentable carbohydrates and less NDF, leading to a higher digestibility and passage rate [25]. In contrast, more mature forage induces a higher CH_4 yield mainly due to an increased C:N ratio, which decreases the digestibility [18]. Different types of forage can also affect CH_4 emission due to the differences in their chemical composition [22]. However, Hammond, Burke [26] found an inconsistent effect of the chemical composition of white clover and ryegrass on CH_4 production. Legume forage has a lower CH_4 yield, which is explained by the presence of condensed tannins, a low fibre content, a high dry matter intake and a fast passage rate [19]. Generally, C4 grasses yield more CH_4 than the C3 plants [27]. Forage processing and preservation also affect CH_4 emission [21]. For instance chopping or pelleting forages can reduce the CH_4 emission per kg of DMI, as smaller particles require less degradation in the rumen [28]. Methanogenesis tends to be lower in the ensiled forages [28], presumably because the ensiled forages are already partially fermented during the ensiling process. Feeding improves the forage quality by feeding young forage with a lower fibre content and a

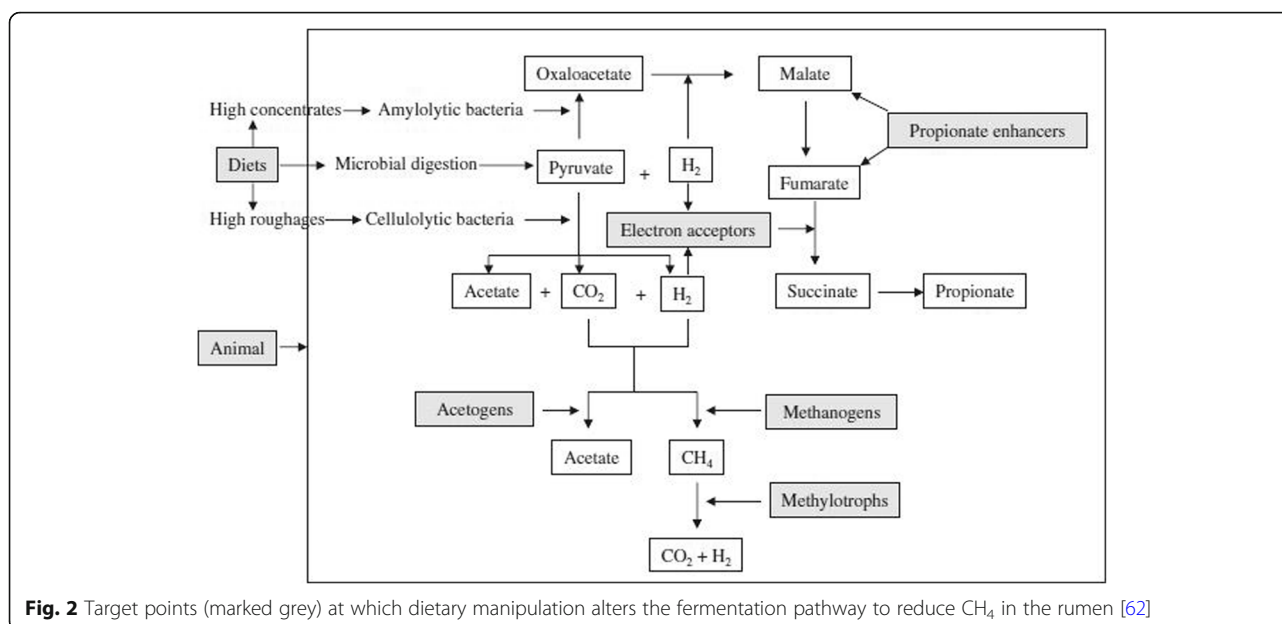

Fig. 2 Target points (marked grey) at which dietary manipulation alters the fermentation pathway to reduce CH₄ in the rumen [62]

higher soluble carbohydrate content; supplementing a small amount of grain with forage is a promising mitigation approach.

Replacement of grass silage by maize silage

Grass silage is usually harvested at a later stage of maturity, resulting in a lower content of digestible organic matter, lower sugar and nitrogen contents and a fraction of lactate as a result of the ensiling process [29]. Consequently, the CH₄ emission from animals that are fed grass silage is likely to be higher. In contrast, maize silage or other whole-crop small-grain silage typically provides higher contents of dry matter with readily digestible carbohydrates, e.g., starch, increasing the DMI and animal performance [19] and ultimately resulting in a lower CH₄ yield from animals. There are three possible ways by which maize silage or whole-crop silage can reduce CH₄ production in the rumen. First, the higher starch content favours propionate production rather than acetate. Second, the increased total DMI and passage rate reduce the ruminal residence time, thereby reducing ruminal fermentation and promoting post-ruminal digestion. Third, replacing grass silage with maize silage improves animal performance, resulting in fewer CH₄ emissions per unit of animal product [30]. Several recent studies have indicated the positive effects of replacing grass silage with maize silage. Hassanat, Gervais [31] reported lower CH₄ emission when alfalfa silage is replaced by 100% corn silage. Maize silage that is harvested during the later stage of maturity has also claimed to reduce CH₄ [29].

Concentrates

High-producing dairy cows have a higher requirement that exceeds their capacity to ingest nutrients from forage only. Therefore, forages must be supplemented with concentrates with a higher density of nutrients and less fibre. Due to less cell walls and readily fermentable carbohydrates (starch and sugar), concentrates favour propionic acid production, decreasing CH₄ emission [21]. The CH₄ reduction effect of concentrates can be described in two ways as below.

Proportion of concentrate

The increased dietary level of concentrate reduces CH₄ production as the energy proportion is mostly utilised by the animal products, such as milk and meat [21]. This effect is independent of genetic merit [32]. Decreased CH₄ emission was observed at 80 and 90% concentrate supplementation, whereas no effect was found at 35 or 60% concentrate supplementation [33]. Most energy-rich concentrates are associated with increased DMI, rate of rumen fermentation and feed-turnover rate, causing a greater change in the rumen environment and microbial composition [21]. An extremely low CH₄ loss of 2–3% of the gross energy intake was reported for feedlot cattle that were fed diet a 90% concentrate [34]. However, high-concentrate diets are low in structural fibre and in the long term disturb rumen function by leading to sub-acute or acute acidosis; therefore, these diets are not sustainable for ruminant production. Feeding concentrate with a suitable F:C ration would obviously be effective in methane mitigation as well as animal productivity.

Concentrate composition

Concentrates that are composed of different ingredients have variable carbohydrate compositions, ranging from structural (cellulose and hemicellulose) to non-structural (starch and sugar) carbohydrates. The degradable rate of both of these types of carbohydrates also varies widely according to the volatile fatty acid profile and CH_4 loss. In beef cattle [34], the digestion of the cell wall leads to a higher acetate: propionate ratio and CH_4 loss compared to other carbohydrate fraction; within non-structural components, sugar is more methanogenic than starch. All of the carbohydrate fractions contribute to CH_4 loss, of which the least contribution is that from starch, probably due to the maintenance of a propionate-dominating VFA profile [29]. Feeding more starch to ruminants reduces enteric CH_4 energy losses compared to feeding a forage diet [35]. Starch fermentation promotes propionate production in the rumen by creating an alternative H_2 sink [36], a lower rumen pH, inhibiting the growth of methanogens [37], decreasing the rumen protozoan numbers and limiting the interspecies H_2 transfer between methanogens and protozoa [38]. In addition, feeding starch, which can escape rumen fermentation, could potentially supply energy to the host animals while avoiding methanogenesis in the rumen. Up to 30% of the starch from corn can escape rumen fermentation and be digested in the small intestine [39]. However, the bypass starch has limited digestibility (up to 60%) in the small intestine [40]. Very limited results are available on the effects of bypass starch on methane mitigation. Further investigation is required for detailed information.

In contrast, sugar as a water-soluble carbohydrate is rapidly and completely degradable in the rumen, enhancing butyrate production at the expense of propionate, thereby making sugar concentrates more methanogenic than starch [41]. Sugars enhance butyrate production at a higher H_2 partial pressure and higher rumen pH, as confirmed by Hindrichsen and Kreuzer [42], who reported a 40% higher CH_4 production with sucrose at a high pH compared to starch, while the opposite result was observed at a low pH with a significantly lower pH for sucrose.

Fat supplementation

The addition of fat to the diet has traditionally been used to increase the dietary energy content to meet the energy demand of high-producing dairy cows. More recently, fat has been used for CH_4 mitigation. If the energy supplementation in a ruminant's diet is changed from carbohydrate to fat, then less fermentation and CH_4 production will occur. The CH_4 -suppressing mechanism of fat is induced by reducing organic matter fermentation, fibre digestibility and consequently the methanogenic pathway and by the direct inhibition of methanogens in the rumen via the hydrogenation of unsaturated fatty acids [34]. The greatest reduction comes

from the unsaturated fatty acids, which act as an H_2 sink in the rumen through dehydrogenation [43], although other studies have reported that hydrogenation contributes only 1% of the H_2 in the rumen [44]. Among fatty acids, the medium-chain $\text{C}_8\text{:C}_{14}$ from coconut or palm oil is the most effective in CH_4 mitigation. Furthermore, fats are not metabolised in the rumen [45] and therefore do not contribute to methanogenesis [34]. Grainger and Beauchemin [46] also reported that fat supplementation often reduces carbohydrate fermentation due to the toxic effects of fat on cellulolytic bacteria and protozoa, while starch fermentation remains unaffected. Consequently, fat depresses CH_4 emission [47]. However, fat supplementation to the ruminant diet is a persistent mitigation strategy [46].

Organic acids

The addition of organic acids, the intermediates of carbohydrate degradation, to the rumen has been suggested as potential feed additives for CH_4 mitigation. Organic acids probably stimulate propionic acid production in the rumen by acting as an H_2 sink, thereby reducing the amount of CH_4 [48]. Newbold, Lopez [49] tested 15 propionate precursors in vitro and concluded that the structure appears to be more effective as an H_2 sink that can reduce CH_4 up to 17%. Fumarate and acrylate produce the most consistent reductions in CH_4 formation in batch cultures, while fumarate is more effective than acrylate in artificial rumens [50]. Furthermore, fumarate (3.5 g/L) reduces the CH_4 output by 38% in continuous fermenters using forage as a substrate [51]. However, a meta-analysis [52] reported a lower CH_4 reduction effect in a continuous batch culture. Including multiple forms of propionate precursors in the diet yielded an additive inhibition of CH_4 emissions as the reductive pathways differ among organic acid sources [50]. In contrast, an in vivo study with growing beef cattle reported a potential beneficial change in rumen fermentation by fumarate, although CH_4 reduction was unaffected [53]. Organic acid supplementation has mostly been tested for CH_4 production in vitro, producing inconsistent results. Therefore, there is the potential to invest more research in farm animals.

Essential oils

Essential oils are plant secondary metabolites, volatile components [29] and aromatic lipophilic compounds [54] with very strong antimicrobial properties [55], which inhibit the growth and survival of most of microorganisms in rumen [56]. The mode of action varies in individual essential oils [57]. However, all essential oils contain chemical constituents and functional groups, such as terpenoids, phenolic and phenols, which have strong antimicrobial properties. Because of their lipophilic nature, essential oils have a high affinity for microbial cell membranes, and functional

groups interact with the microbial cell membrane [58]. Methanogenesis decreases with the application of essential oil, especially by reducing microbial populations. However, no effect has been observed so far on the major aspects of rumen fermentation [59]. Limited studies have investigated the effect on CH₄ reduction in vivo. However, methanogenesis is inhibited by altering protein degradation and amino acid determination [59]. Further research needs to investigate the potential use of essential oils in mainstream livestock farming.

Ionophores

Antibiotics, such as monensin, are antimicrobial compounds that are typically used in beef and dairy cattle production to modulate feed intake and improve feed efficiency and animal productivity [60]. Monensin increases the acetate: propionate ratio in rumen fermentation by increasing reducing equivalents that help to form propionate [19]. Monensin may also decrease ruminal protozoa. This antibiotic is typically added to the diet as premix or via a slow-releasing capsule and has an anti-methanogenic effect [19]. Ionophores do not alter the diversity of methanogens [61] but change the bacterial population from Gram-positive to Gram-negative with a consequent change in the fermentation from acetate to propionate, thereby reducing CH₄ [62]. A high dose of monensin reduces CH₄ production (g/d) by 4–10% in dairy and beef cattle [63, 64]. Furthermore, Guan, Wittenberg [65] reported a 30% CH₄ reduction in beef cattle that were fed monensin (33 mg/kg), which was related to the number of ciliated protozoa. The inhibitory effects of ionophores on CH₄ production may not persist over time, and microorganisms adapt to ionophores [19, 34, 65]. However, the possible transient effect of ionophores and increasing public pressure to reduce the use of antimicrobial feed additives in agricultural production will obviously limit the scope for a long-term solution to CH₄ mitigation [19].

Probiotics

The use of probiotics for CH₄ mitigation has recently been described [66]; [43]. The specific CH₄ reduction potential of probiotics has not been well documented due to the unsuccessful introduction of acetogens to the rumen as competitors of methanogens [67]. Probiotics, such as lactic acid producers (*Lactobacillus plantarum*, *L. casei*, *L. acidophilus* and *Enterococcus faecium*), acetate and propionate producers (*Selenomonas ruminantium* and *Megasphaera elsdenii*) and yeast (*Saccharomyces cerevisiae* and *Aspergillus oryzae*) are widely used for the health of both human and animals [68]. Probiotics based on *Saccharomyces cerevisiae* are increasingly used in ruminant diets to improve rumen fermentation, dry matter intake and milk yield [19]. The underlying mechanism is probably the alteration of

H₂ production by the increased number of bacteria due to the partitioning of degraded carbohydrates between the microbial cells and fermented products [69]. Due to their modest price and wide use in ruminant production, the acceptance of CH₄-reducing probiotics has a high probability in CH₄ abatement. However, further research is needed to investigate the best possible products [19].

Exogenous enzymes

Enzymes, such as cellulase and hemicellulase, are currently being used in ruminant diets. When properly formulated, enzymes can improve fibre digestibility and animal productivity [70]. Enzymes that improve fibre digestibility typically lower the acetate: propionate ratio in the rumen, ultimately reducing CH₄ production [71]. Subsequently, in a recent review, Beauchemin, Kreuzer [19] suggested the possibility of developing a commercial enzyme additive to reduce CH₄. However, searching for potential enzymes for methane abatement warrants future research.

Alternative H₂ sink

Alternative H₂ sinks, for example, nitrate and sulphate, are used at lower concentrations in the basic diets of ruminants. As alternative electron acceptors, nitrate and sulphate have a greater reduction potential and are thermodynamically highly favourable for some rumen microbes [72]. Regarding methane mitigation, Leng [73] described the potential of nitrate supplementation in the ruminant diet. Furthermore, van Zijderveld, Gerrits [74] demonstrated that the reduction effect of nitrate and sulphate is electronically more favourable than is CH₄ production, which can potentially change the competitiveness of H₂ scavengers. In recent years, nitrate and sulphate have been increasingly tested for CH₄ abatement. A 32% methane reduction was reported for nitrate, 16% for sulphate and 47% for a combination of nitrate and sulphate fed to lambs [74]. The same author in a subsequent study indicated an approximately 16% CH₄ (g/d and g/kg DMI) reduction in dairy cows [75]. However, nitrate supplementation has not been established in many countries (e.g., in Denmark) due to toxic effects that could lead to animal death. One potential toxic effect occurs via the reduction of nitrate to nitrite, which causes methemoglobinemia, a condition in which blood haemoglobin cannot carry oxygen [74]. Because a lower amount of nitrate in the diet is safe for the animal [76], nitrate supplementation can be an effective CH₄ mitigation measure. However, more research is needed to determine the inclusion levels for different ruminant species.

Plant secondary metabolites

The potential effect of plant secondary metabolites (PSM) in CH₄ reduction has been recently recognised [19]. The CH₄-suppressing effect of PSM is mainly

associated with antimicrobial properties that kill the bacteria [77], protozoa [78] and fungi [79] in the rumen. Plant secondary metabolites contain phenolic compounds the main active components that have antimicrobial activity [80]. Plants produce a variety of secondary compounds, among which condensed tannins [81] and saponins [82] have received much attention.

Condensed tannins

An interesting development in CH₄ mitigation research is the development of forages with higher levels of tannins, such as clover and other legumes, including trefoil, vetch, sulla and chicory [29]. The anti-methanogenic activity of tannins has recently been investigated in vitro and in vivo [83]. The CH₄-suppressing mechanism of tannins has not been described clearly; however, this mechanism may inhibit ruminal microorganisms [77]. Tannins may inhibit, through bactericidal or bacteriostatic activities, the growth or activity of rumen methanogens and protozoa [84]. Methane production was reduced (up to 55%) when ruminants were fed tannin-rich forages, such as lucerne, sulla, red clover, chicory and lotus [81]. Although tannins appear promising for CH₄ mitigation, these impede forage digestibility and animal productivity when fed at a higher concentration, limiting their future wide-scale use in CH₄ abatement [19]. However, more research may identify the balance between CH₄ reduction and possible anti-nutritional side effects as associated with tannin supplementation.

Saponins

Saponins are naturally occurring surface-active glycosides that are found in a wide variety of cultivated and wild plant species that reduce CH₄ production in the rumen [29, 79]. Saponins have a potent antiprotozoal activity by forming complex sterols in protozoan cell membranes [83] and, to some extent, exhibit bacteriolytic activity in the rumen [66]. Saponins are antiprotozoal at lower concentrations [85], whereas higher concentrations can suppress methanogens [77]. Saponins inhibit ruminal bacterial and fungal species [79] and limit the H₂ availability for methanogenesis in the rumen, thereby reducing CH₄ production [77]. Methane reduction of up to 50% has been reported with the addition of saponins [86]. However, a wider range of CH₄ reduction (14–96% depending on the plant and the solvent that was used for extraction) has been reported [62].

Rumen manipulation

Manipulating the microbial diversity in the rumen through chemical means (e.g., halogenated compounds and chloroform) by introducing competitive or predatory microbes or through direct immunisation can reduce methanogenesis in ruminants [20]. A preliminary study

suggested that vaccination against methanogens can reduce CH₄ emission up to 8% [87]. However, the long-term effect of vaccination on CH₄ reduction is still uncertain [88]. Furthermore, methanogen populations in the rumen are influenced by diet and geographic location (Wright et al., 2007); therefore, it is challenging to develop a broad-spectrum vaccine against all methanogens. Instead, the development of a vaccine against the cell-surface proteins of methanogens may improve the efficacy of vaccination for CH₄ mitigation [50]. Biological control bacteriophages or bacteriocins could be effective in the direct inhibition of methanogens and in redirecting H₂ to other reductive rumen microbes, such as propionate producers or acetogens [50]. However, most of these options are still conceptual, and significant research is required.

Halogenated compounds, such as bromochloromethane and chloroform, are potent inhibitors of CH₄ production in ruminants. Methane reduction has been reported with bromochloromethane mainly due to the reduction of methanogen abundance [89]. An approximately 26% CH₄ reduction was reported by McAllister and Newbold [50] through the chemical inhibition of protozoa because the methanogens are often attached to the surface or endosymbionts within ciliated protozoa [50].

Defaunation also reduces CH₄ emission. Two major advantages of defaunation are that it increases nutrient utilisation by animals and limits H₂ transfer between protozoa and methanogens. The methanogens that are attached to ciliated protozoa contribute approximately 9–37% of the methanogenesis in the rumen [38]. Protozoa-free lambs and sheep exhibits 26 and 20% CH₄ reduction, respectively [50]. The elimination of the protozoan population in CH₄ mitigation is interesting, but the absence of protozoa in the rumen can hinder digestibility and animal performance.

Reductive acetogenesis, in which H₂ and CO₂ form acetate rather than CH₄ as a source of energy, has been suggested as an alternative to methanogenesis [90]. The production of acetate instead of CH₄ can increase the energy supply to the animals. Joblin [90] suggested that if the CH₄ emissions in ruminant were fully replaced by acetate, this could represent an energetic gain of 4–15%. However, acetogenesis in CH₄ reduction has not been successful due to the failure in acetogens competing for H₂ in the rumen. Research in acetogenesis as a CH₄ mitigation measure is still in the initial phase and warrant more research.

Animal manipulation

Several options, such as culling low-producing animals, increasing animal productivity and breeding animals with lower CH₄, have been suggested for CH₄ mitigation through animal manipulation. Methane emission is directly proportional to the number of animals in a herd. The

replacement of non-productive and low-producing animals would cut the total CH₄ budget from the herd. Maintaining high-producing animals will increase the total production, but the CH₄ emission per unit of animal product will decrease [62, 91]. Therefore, proper nutrition management to improve productivity is an option to reduce the CH₄ emission per unit of animal product.

Several studies have demonstrated a substantial variation in CH₄ production in sheep and cows [92–94], which may be linked to phenotypic traits and heritability. This animal variation in CH₄ production suggests a possibility of breeding animals with low CH₄ emission. However, Eckard, Grainger [20] suggested that breeding for reduce CH₄ production is unlikely to be compatible with other breeding objectives.

Conclusions

A Number of methane mitigation options are available and currently in practice. No single option appears to provide a simple and enduring solution. Selection and breeding of low methane emitter animals is one of the solutions which requires longer time frame. Use of chemicals, ionophors, plant secondary metabolites or such application attributes transitory effects on methane reduction. However, overall dietary manipulation by selecting and utilizing high quality forages, strategic supplementation of forages, changing concentrate proportion with special emphasis on changing carbohydrate composition should be considered as an immediate and sustainable methane mitigation approach of enteric CH₄ emitted from ruminant livestock. Feeding a diet with more starch and less fibres not only produce less methane per kg feed DM but also form a basis for higher feed intake and higher production per animal and hence will be the most efficient way to reduce the methane production per kg of meat or milk produced.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
