Abstract

Intercell interference coordination (ICIC) is considered as a promising technique to increase the spectral efficiency of OFDMA cellular systems. The soft frequency reuse (SFR) and fractional frequency reuse (FFR) are representative and efficient management techniques for ICIC. Herein, to enhance the performance of the SFR scheme, we propose a call admission (CAC) scheme. In this CAC scheme, called Spectrum handoff-SFR(S-SFR), the spectrum handoff technique is applied to the user equipment (UE) located near the cell center. We derive the traffic analysis model to describe the S-SFR. In addition, a two-dimensional (2-D) Markov chain and an outage analysis are used in our analytical model. From the traffic analysis, the significant performance measures are the outage probability, call blocking probability, system throughput and resource utilization. Based on those, the outage probability and system throughput are obtained using resource utilization as an interference pattern. The analytical results are verified with computer simulation results. Finally, we compare our proposed scheme with other ICI schemes.

Keywords: Spectrum handoff, intercell interference coordination(ICIC), call admission control(CAC), 2-D Markov chain, soft frequency reuse(SFR)

1. Introduction

1.1 Background

Current and emerging wireless cellular systems (i.e., LTE-A, WiFi, 5G) characterize more dense base station (BS) deployments providing higher network capacity as mobile user traffic increases. Orthogonal frequency division multiple access (OFDMA), which combined scheduling and resource allocation techniques, is the most common way to achieve high system performance [1] and [2]. In OFDMA-based networks, the orthogonality between subcarriers renders the intracell interference negligible. However, because these networks are targeting a frequency reuse factor of 1 (FRF 1), which refers to reusing the whole spectrum in each cell, it also causes high intercell interference (ICI), particularly in cell edge areas. The performance of wireless cellular networks may drop dramatically due to the impact of high ICI. Therefore, ICI coordination (ICIC) is a significant issue in the design of cellular systems, especially 4G and 5G systems [3].

To overcome ICI, various ICIC schemes have been studied in the literature under various spectrum conditions and network structures. In [4], the authors classify the ICIC schemes along several dimensions to differentiate the schemes between static versus adaptive and centralized versus coordinated. Static ICIC is based on frequency reuse (FR) schemes such as frequency reuse factor 3 (FRF 3) [5]. Adaptive FR that does not require cooperation between BSs is based on the adaptive resource and/or power allocation schemes, such as soft frequency reuse (SFR) and fractional frequency reuse (FFR) [6]-[8]. A centralized scheme is operated through a central control entity that manages multiple BSs simultaneously [9][10]. Finally, coordinated distributed schemes utilize the specific indicators exchanged between the neighboring BSs via the X2 interface for reducing ICI [11]. Among the various ICIC schemes mentioned above, FFR and SFR are considered as an attractive technique for state-of-the-art OFDMA-based cellular systems. However, there is limited prior research on the performance analysis through traffic models in FFR and SFR. So, we consider the performance analysis through a traffic model in adaptive FR schemes as well as a call admission control (CAC) algorithm.

Fig. 1 shows an example of frequency assignment for FFR and SFR as the adaptive FR schemes. As shown, a cell is divided into two regions: the *inner region* and the *outer region*. In both schemes, the users in the outer region can be assigned a different frequency sub-band with the adjacent cells. As shown in **Fig. 1**, for the inner region in FFR, the users in that region can use the frequency sub-band in the manner of FRF 1 in the neighboring cells (**Fig. 1** (a)) while, in SFR, the users can use the whole frequency band and share the bandwidth with the neighboring cells as FRF 1 (**Fig. 1** (b)). From the FFR scheme, the users in the inner region can avoid the interferences by the signals for the users in the outer region of the neighboring cell. For the users in the outer region, they receive the interfering signals from the neighboring cell using the same frequency sub-band. Thus, the number of interfering signals received from the neighboring cells is decreased. However, since the frequency sub-band is limited, when the resources are heavily utilized, the FFR scheme may result in high call blocking probability, which is defined as the ratio of the number of calls lost in the system to the total number of newly initiated calls [23]. For the SFR scheme, as the users in the inner region can use the whole frequency band compared with the FFR scheme, a call blocking probability of SFR is decreased compared to that of FFR. In addition, the user in the outer region of SFR may

undergo the interference by signal for the user in the inner region of the neighboring cell. Accordingly, we consider an SFR scheme to maximize the system throughput, while maintaining some quality of service (QoS) constraints. More specifically, we propose a CAC algorithm with a preemption technique in SFR to reduce the call blocking probability and improve the system throughput.

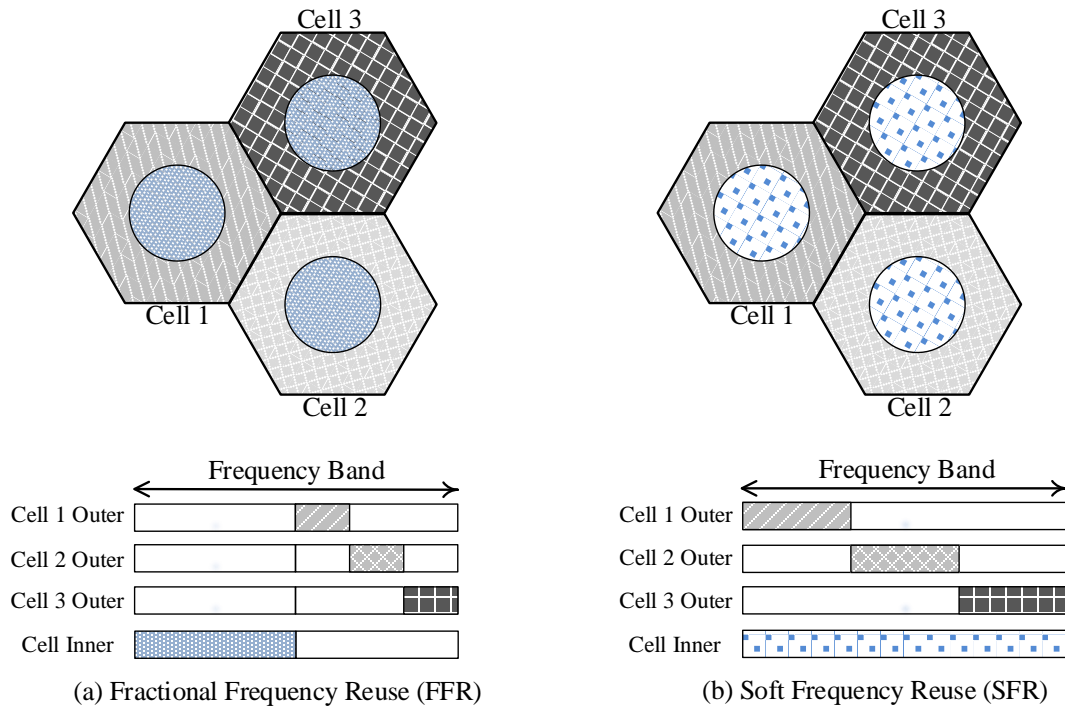

Fig. 1. Example of frequency assignment for FFR and SFR schemes

1.2 Related Work

To effectively coordinate ICI and improve the spectrum efficiency, many studies on the performance of FFR and/or SFR systems has been reported [12]-[25]. In [12] and [13], Novlan and Zhu et al. analyzed the FFR and SFR performances considering the two types of FRs, depending on the inner and outer regions. In [14], the authors showed the improved performance of the outage probability and the average cell-edge user throughput through coordinated SFR (CoSFR), in which the multicell networks with nonuniform user distribution was considered. In [15], the authors developed a model for analyzing FFR-aided OFDMA-based multi-cellular networks that incorporates shadowing effects and considers the irregular cellular networks. In [24], the authors proposed an analytical model for evaluating the performance of FFR-aided heterogeneous networks (HetNet) that considers both co-tier and cross-tier interference. [25] developed a framework for allowing the design of optimal 5th-percentile user rate constrained FFR/SFR-aided multi-cellular OFDMA-based networks using channel-aware PF scheduling. In [16] and [17], the FFR and/or SFR schemes were applied to heterogeneous cellular networks, and the coverage probability for these schemes was derived under the Rayleigh fading. In [22], to maximize the overall network throughput and minimize the outage probability, the authors proposed a resource allocation and power control scheme in FFR-based heterogeneous cellular networks, in which the limiting the cross-tier interference below a predefined threshold. [18] studied a global energy efficiency

optimization algorithm in multicell networks with multiple users, in which the convex optimization method was considered. Additionally, in [19], to minimize network interference, the authors established the multilayer SFR scheme combined with cell sectoring where the spectrum is allocated intelligently among several regions. Literatures that focus on the analysis of SFR with the traffic model are limited. In [21], the authors proposed a CAC using the one-dimensional Markov chain model in FFR-based cellular systems to improve the performance of call blocking probabilities and resource utilizations. [7] and [20] developed an analytical model to describe the CAC in SFR-based systems and characterized the outage probability and/or new call blocking probability. [7] models a 3-D Markov chain for traffic analysis, while our proposed model uses a 2-D Markov chain. Specifically, in [7], SFR causes a forced termination problem of an ongoing call. In this paper, we propose a method to overcome the forced termination problem.

1.3 Primary Contributions

In this research, we propose the Spectrum handoff-SFR (S-SFR) under a CAC algorithm with a preemption technique to enhance the performance of OFDMA cellular network. From the modeling point of view, we herein consider the small-scale fading as in [12]-[19]. In contrast to [12]-[19], we will furthermore consider a traffic model as well as a CAC algorithm. In addition, we consider the outage analysis using the interference patterns. The four key contributions in our paper are summarized as follows:

1. A CAC algorithm is proposed, in which a preemption technique is applied to the user equipment (UE) in the inner zone. In contrast to [7], we model a 2-D Markov chain for the traffic analysis of the proposed scheme-based cellular systems, in which we assume that the call interarrival time and call duration are exponentially distributed. In the analysis, the call blocking probabilities for users and resource utilization are obtained. These are used for some design criteria, such as the inner region size, to maximize the system throughput.
2. We derive a model of the signal to interference and noise ratio (SINR) for a user by considering the cellular geometry, ICI, and fading effects. This paper, in contrast to [12]-[22], assumes that some neighboring cells statistically generate ICIs, depending on the resource utilization of each cell.
3. The system throughput is defined, in which the QoS pertains to the call blocking of user calls and the outage probabilities. In other words, the system throughput can be obtained from the effective carried load.
4. We compare the performance with the different adaptive FR schemes by differentiating the inner region size and the traffic load, where the FFR and SFR schemes are considered. Our proposed scheme outperforms the other schemes with regard to the system throughput based on some criteria.

The remainder of this paper is organized as follows: Section 2 introduces the system model with the proposed scheme, our assumptions, and an optimization problem for designing this system. In section 3, we analyze this system to solve our optimization problem. In section 4, we discuss the numerical studies and present some concluding remarks in section 5.

2. System Model

2.1 Cellular network topology

We consider a cellular network with a Spectrum handoff-SFR(S-SFR)-based system. We consider the 2-tier cell cluster model used in many inter-cell interference studies [12-22]. As shown in Fig. 2, each eNodeB (eNB) is located at the cell center, in which the length of one side of a hexagonal cell is R . When the cell is deployed in 2-tier around the target cell, the number of cells in the system model is 19. The radius of a circular cell whose area is the same as a hexagonal cell R_0 is given by $\sqrt{3\sqrt{3}R^2/2\pi}$. Each cell is further divided into two regions: the inner region of radius z and the outer region, which is outside the inner region. Herein, the UE located in the inner and the outer regions are called the *inner UE* and *outer UE*, respectively. As a more realistic model, to determine whether a UE is in the inner region or the outer region, the eNB can use the received signal strength (RSS), which is measured and then reported by the UE to estimate the distance.

Fig. 2. Network topology for S-SFR-based cellular systems

In our model, we assume that the reuse factor of 3 is used in our S-SFR-based cellular system, and one set of frequency physical resource block (PRB), F_i , is assigned to each of the outer regions of the 19-cell cluster in a regular pattern, as shown in Fig. 2. As [7], the UE in the inner region (inner UE) may use an available PRB in F while those in the outer region (outer UE) may use any available PRB only in the outer PRB, F_i , $i = 0, 1, 2$. Suppose that the outer UE on the tagged cell use the PRBs in F_0 . Subsequently, the PRBs in F_1 and F_2 are assigned alternately to outer UE in the odd- and even-numbered first-tier cells, respectively. For the

second-tier cells, the PRBs of F_0 are assigned to the outer UE in cells numbered from 13 to 18 in Fig. 2, while the PRBs of F_1 and F_2 are assigned alternately to the outer UE in cells numbered from 7 to 12. As shown in Fig. 2, the 18 neighboring cells are divided into three sets based on the distance from the target cell, eNB_0 . The first set of cells is the six neighboring cells numbered from 1 to 6 in the first tier, which are $d_1 = \sqrt{3}R$ away from the center of the target cell. The second set includes the six cells in the second tier, which are numbered from 7 to 12. These cells are $d_2 = 2d_1$ away from eNB_0 . The third set is the set containing the remaining six cells in the second-tier cells, which are numbered from 13 to 18 and adjacent to the d_1 cells and d_2 cells. These are $d_3 = 3R$ away from eNB_0 .

2.2 Call admission control of S-SFR

For traffic modeling, a number of UEs can initiate multiple calls when trying to occupy radio resources, where the basic unit of radio resources is referred to as the PRB. We assume that each of the eNBs has a total of C PRBs, which consists of C_i , inner PRBs and C_o , outer PRBs, where $C_i = C - C_o$. We also assume that a UE shall access to its serving eNB, whose access interval follows an exponential distribution with mean $1/\lambda$ (sec/call), and the UEs are uniformly distributed over the cell. Let ω be the fraction of the area for the inner region to the cell coverage, i.e., $\omega = (z/R_0)^2$. The new call arrival rates of the inner and outer UE are assumed to be $\lambda_i = \omega\lambda$ and $\lambda_o = (1-\omega)\lambda$, respectively. Each user who successfully receives a PRB shall hold it for exponentially distributed random times with mean $1/\mu$ (sec).

When a new inner UE is originated, it will first attempt to occupy an inner PRB. If one or more inner PRBs are available, it will be admitted. If no inner PRB is available, it will attempt to occupy an outer PRB. It will be blocked once no outer PRBs are available; this event is called an inner call blocking. When an inner UE occupying an inner PRB is released, an ongoing inner UE occupying the outer PRB is reconnected using a released PRB. This is called *spectrum handoff*. Therefore, an inner UE can use either an inner or outer PRB if they are available.

For a newly arrived outer UE, it will first attempt to occupy an outer PRB. At this time, if all outer PRBs are in use by the ongoing outer UE, it will be blocked. This is called an outer call blocking. If at least one outer PRB is available, it will be admitted. If no outer PRBs are available but one or more outer PRBs are occupied by the ongoing inner UEs, one of the inner UEs will be randomly chosen and forced to release the outer PRB that it is occupying. The released PRB is then assigned to the newly arrived outer UE. The probability that the inner UE is forcibly terminated is referred to as *forced termination probability*.

2.3 Signal to Interference plus Noise Ratio Model

For a physical-layer modeling, the average power received at a UE from a eNB j , i.e., eNB_j , is expressed as

$$P_j = P_t r_j^{-\alpha} h_j, \quad (1)$$

where P_t is the transmission power of eNB, and h_j indicates the small-scale fading, which is assumed to be exponentially distributed with mean δ_j , i.e., Rayleigh fading. $r_j^{-\alpha}$ denotes a path-loss at a distance r_j between eNB_{*j*} and a UE in eNB₀ where α denotes the path-loss exponent.

Based on Eq. (1), the SINR of the average power received at a UE from the interference set \hat{o} with n_i interfering signals is as follows:

$$SINR = \frac{P_t r_o^{-\alpha} h_o}{\sum_{j \in \hat{o}(n_i)} P_t r_j^{-\alpha} h_j + \sigma^2}, \quad (2)$$

where σ^2 denotes additive noise.

2.4 S-SFR Problem Formulation

The system throughput denoted by S_{th} is obtained from the effective carried load. Accordingly, for a given Erlang load, which is defined as the number of calls per unit call holding time, $\mathcal{G} = \lambda/\mu$, and z , S_{th} can be expressed as

$$S_{th}(\mathcal{G}, z) = \left[\lambda_i (1 - P_{Bi}) (1 - P_f) (1 - P_{oi}) + \lambda_o (1 - P_{Bo}) (1 - P_{oo}) \right] / \mu, \quad (3)$$

where P_{Bi} and P_{Bo} are the call blocking probabilities of the inner and outer UE, respectively; P_f denotes the forced termination probability. In addition, P_{oi} and P_{oo} are the outage probabilities of the inner and outer UE, respectively. It is noteworthy that S_{th} depends on Erlang load \mathcal{G} and z . Thus, an optimization problem for S_{th} can be formulated as follows:

$$\begin{aligned} & \text{Max} && S_{th}(\mathcal{G}, z), \\ & \text{Subject to} && P_{Bi}, P_{Bo} \leq \varepsilon_B \text{ and } P_o \leq \varepsilon_o, \\ & \text{Variables} && \mathcal{G}, z, \end{aligned} \quad (4)$$

where ε_B denotes the threshold of the call blocking probability, ε_o denotes the tolerance of the outage probability. The call blocking probability and the outage probability will be derived in the next section.

3. Performance Analysis

3.1 Traffic analysis

Assuming the characteristics of traffic, the process of PRB occupation can be modeled as a continuous-time Markov chain. For the CAC of S-SFR, the state transition diagram is described by an integer pair (n_i, n_o) as shown in Fig. 3, where n_i and n_o denote the number of inner UE and outer UE, respectively. As the outer UE have the priority to use the outer PRB,

$$P_{Bi} = \sum_{n_i=C_i}^C P(n_i, C-n_i), \quad P_{Bo} = \sum_{n_i=0}^{C_i} P(n_i, C_o). \quad (7)$$

From Eq. (7), we can obtain the aggregate call blocking probability, P_B , as follows:

$$P_B = \omega P_{Bi} + (1-\omega) P_{Bo}. \quad (8)$$

3.1.2 Forced termination probability

The forced termination probability, P_f , is considered as the total UE forced termination rate divided by the total UE connection rate. Therefore, it is given as follows:

$$P_f = \frac{\lambda_o/\mu \sum_{n_i=C_o+1}^C P(n_i, C-n_i)}{\lambda/\mu(1-P_B)}. \quad (9)$$

3.1.3 Resource utilization

To obtain the resource utilization, we first find the mean number of the inner UE and outer UE in the target cell, which are denoted by \overline{N}_i and \overline{N}_o , respectively, and obtained by

$$\overline{N}_i = E[N_i] = \sum_{n_i=0}^{C_i} n_i \sum_{n_o=0}^{C_o} P(n_i, n_o) + \sum_{n_i=C_i+1}^C n_i \sum_{n_o=0}^{C_o-n_i} P(n_i, n_o), \quad (10)$$

$$\overline{N}_o = E[N_o] = \sum_{n_o=0}^{C_o} n_o \sum_{n_i=0}^{C-n_o} P(n_i, n_o). \quad (11)$$

They can also be obtained as follows:

$$\overline{N}_i = \lambda_i (1-P_{Bi}) (1-P_f), \quad \overline{N}_o = \lambda_o (1-P_{Bo}).$$

It is noteworthy that \overline{N}_i includes not only the inner UE using the inner PBR, \overline{N}_{ii} , but also the inner UE using the outer PBR, \overline{N}_{io} . Thus, the following are obtained:

$$\overline{N}_{ii} = \sum_{n_i=0}^{C_i} n_i \sum_{n_o=0}^{C_o} P(n_i, n_o) + \sum_{n_i=C_i+1}^C C_i \sum_{n_o=0}^{C_o-n_i} P(n_i, n_o), \quad (12)$$

$$\overline{N}_{io} = \overline{N}_i - \overline{N}_{ii}. \quad (13)$$

From Eq. (12) and (13), given that a PRB is assigned to an inner UE, the probability that the PRB is an inner PRB, ν_i , is obtained by

$$v_i = \frac{\overline{N_{ii}}}{N_i}. \quad (14)$$

Additionally, an outer PRB assigned to the inner UE can be used until this UE is forced terminated by a new arriving outer UE. Thus, the time used by the inner UE is given by

$$\overline{N_{io_f}} = \underbrace{\left[\lambda_i (1 - P_{Bi}) P_f \right]}_{(a)} \times \underbrace{(\mu - \lambda_o)}_{(b)}, \quad (15)$$

where (a) means the mean number of the inner UE forced terminated by the outer UE and (b) means the time used by each forced terminated inner UE. From Eq. (12), (13) and (15), we can obtain the resource utilization of the inner PRB, ρ_i , and that of the outer PRB, ρ_o , respectively, as follows:

$$\rho_i = \frac{\overline{N_{ii}}}{C_i}, \quad \rho_o = \frac{\overline{N_o} + \overline{N_{io}} + \overline{N_{io_f}}}{C_o}. \quad (16)$$

As mentioned earlier, ρ_i and ρ_o are used as statistically generated interferences from some neighboring eNBs. From Eq.(16), the total resource utilization, ρ , is given by

$$\rho = \frac{\rho_i \cdot C_i + \rho_o \cdot C_o}{C}. \quad (17)$$

Table 1. Summary for interference scenarios

PRB used cases	Utilization	Cell Number
Inner PRB used	ρ_i	2,4,6,8,10,12,13,14,15,16,17,18
	ρ_o	1,3,5,7,9,11
Outer PRB used	ρ_i	1~12
	ρ_o	13~18

3.2 Outage Analysis

To obtain the outage probability for a given threshold γ and interference set, $\partial(n_t)$, we first find the complementary outage probability, $P_o^C[\gamma | \partial(n_t)]$. This can be expressed as

$$P_o^C[\gamma | \partial(n_t)] = \Pr[SINR > \gamma | \partial(n_t)] \\ = \int_0^{2\pi} \int_{r_{min}}^{r_{max}} \Pr \left[\underbrace{\frac{P_t r_o(r, \theta)^{-\alpha} h_o}{\sum_{j \in \partial(n_t)} P_t r_j(r, \theta)^{-\alpha} h_j + \sigma^2}}_{(c)} > \gamma \right] f_p(r, \theta) dr d\theta, \quad (18)$$

where (r, θ) is the polar coordinated UE in the target eNB, i.e., eNB₀ and $f_p(r, \theta)$ denotes the joint probability density function (PDF) of (r, θ) , given by

$$f_p(r, \theta) = \frac{1}{2\pi} \times \frac{2r}{R_0^2}, \quad r \leq R_0, \quad 0 \leq \theta \leq 2\pi. \quad (19)$$

Because two regions exist, in Eq. (18), when the inner UE is considered, r_{min} and r_{max} are 0^+ and z , respectively. For the outer UE, they are z and R_0 , respectively. Additionally, the interference set, ∂ , denotes a set of all active eNBs, which depend on the resource utilization of each eNB. For example, suppose that a UE is using an inner PRB F_1 . Two types of interference scenarios exist: (i) the interferences occur from cells 2, 4, 6, 8, 10, 12, 13, 14, 15, 16, 17, and 18 with resource utilization of inner PRB, ρ_i , (ii) the interferences occur from cells 1, 3, 5, 7, 9, and 11 with ρ_o . Similarly, for the case where the UE uses the outer PRB, the interference scenarios are summarized in **Table 1**. We assume that ρ_i and ρ_o are used as statistically generated interferences from some neighboring eNBs. Thus, the probability that for a UE using an inner PRB, where there are n_I interferences, which are n_{I-i} interferences from the inner PRB and n_{I-o} interferences from the outer PRB, $\Pr[\partial(n_I): n_{I-i}, n_{I-o}]$, is

$$\binom{12}{n_{I-i}} \rho_i^{n_{I-i}} (1-\rho_i)^{12-n_{I-i}} \times \binom{6}{n_{I-o}} \rho_o^{n_{I-o}} (1-\rho_o)^{6-n_{I-o}}. \quad (20)$$

Based on 2-3, we can rewrite (c) in Eq. (18) as follows:

$$(c) = \Pr \left[h_o > \gamma \left(\sum_{j \in \partial(n_I)} d_j(r, \theta)^{-\alpha} h_j \right) + \gamma \sigma^2 p_t^{-1} r_o(r, \theta)^\alpha \right], \quad (21)$$

where $d_j(r, \theta)^{-\alpha} = P_{r_j}(r, \theta)^{-\alpha} / P_{r_o}(r, \theta)^{-\alpha}$. Let $A = \gamma \sigma^2 p_t^{-1} r_o(r, \theta)^\alpha$. Therefore,

$$\begin{aligned} & \Pr \left[h_o > \gamma \left(\sum_{j \in \partial(n_I)} d_j(r, \theta)^{-\alpha} h_j \right) + A \right] \\ &= \int_{h_1=0}^{\infty} \cdots \int_{h_{n_I}=0}^{\infty} \Pr \left[h_o > \gamma \left(\sum_{j \in \partial(n_I)} d_j(r, \theta)^{-\alpha} h_j \right) + A \mid h_1, h_2, \dots, h_{n_I} \right] \prod_{j=1}^{n_I} f_j(h_j) dh_j \quad (22) \\ &= e^{-\left(\frac{1}{\delta_j}\right)^A} \int_{h_1=0}^{\infty} \cdots \int_{h_{n_I}=0}^{\infty} e^{-\left(\frac{1}{\delta_j}\right)^\gamma \left(\sum_{j \in \partial(n_I)} d_j(r, \theta)^{-\alpha} h_j \right)} \prod_{j=1}^{n_I} f_j(h_j) dh_j, \end{aligned}$$

where $f_j(h_j)$ denotes the PDF of h_j , i.e., $f_j(h_j) = (1/\delta_j)e^{-(1/\delta_j)h_j}$. When we integrate Eq. (22) with respect to h_j first, we obtain

$$e^{-\left(\frac{1}{\delta_o}\right)A} \int_{h_{n_l}=0}^{\infty} \dots \int_{h_2=0}^{\infty} e^{-\left(\frac{1}{\delta_o}\right)\gamma\left(\sum_{j=\partial(n_l-1)} d_j(r,\theta)^{-\alpha} h_j\right)} \frac{1}{\frac{\delta_1}{\delta_o} \gamma d_1(r,\theta)^{-\alpha} + 1} \prod_{j=2}^{n_l} f_j(h_j) dh_j, \quad (23)$$

where $\int_0^{\infty} e^{-Gx} dx = 1/G$ is used. We can simplify (c) in Eq. (18) as follows:

$$(c) = \prod_{j=1}^{n_l} \frac{e^{-\left(\frac{1}{\delta_o}\right)\gamma\sigma^2 P_i^{-1} r_o(r,\theta)^\alpha}}{\frac{\delta_j}{\delta_o} \gamma d_j(r,\theta)^{-\alpha} + 1}. \quad (24)$$

Accordingly, Eq. (19) can be rewritten as

$$P_o^C(\gamma | \partial(n_l)) = \int_0^{2\pi} \int_{r_{\max}}^{r_{\min}} \prod_{j=1}^{n_l} \frac{e^{-\left(\frac{1}{\delta_o}\right)\gamma\sigma^2 P_i^{-1} r_o(r,\theta)^\alpha}}{\frac{\delta_j}{\delta_o} \gamma d_j(r,\theta)^{-\alpha} + 1} f_p(r,\theta) dr d\theta. \quad (25)$$

By using the total probability law for Eq. (20), we can obtain $P_o(\gamma)$ as follows:

$$\begin{aligned} P_o(\gamma) &= 1 - P_o^C(\gamma) \\ &= 1 - \sum_{n_l=0}^{18} \sum_{n_{l-i}=0}^{n_l} \sum_{n_{l-o}=0}^{n_l-n_{l-i}} P_o^C[\gamma | \partial(n_l)] \Pr[\partial(n_l): n_{l-i}, n_{l-o}]. \end{aligned} \quad (26)$$

Based on Eq. (14) and (26), once the outage probability of the inner UE using the inner PRB, $P_{o_ii}(\gamma)$ and that of the inner UE using outer PRB, $P_{o_io}(\gamma)$, are obtained, we have

$$P_{oi}(\gamma) = v_i P_{o_ii}(\gamma) + (1-v_i) P_{o_io}(\gamma). \quad (27)$$

Once the outage probability of the inner UE, P_{oi} , and that of the outer UE, P_{oo} , respectively, are obtained, we can obtain the total outage probability, P_o , as follows:

$$P_o = \frac{\lambda_i P_{oi} + \lambda_o P_{oo}}{\lambda}. \quad (28)$$

4. Numerical Results

From the previous section, we obtained an analytical model as a function of ϑ and z . Here, we will analyze the performance of the S-SFR-based system and compare it with the simulation results to verify its accuracy. Additionally, we will compare the performance of our scheme with other SFR schemes. The system parameters are chosen as shown in **Table 2**. It is noteworthy that in the figures, the lines are obtained from the equations given in the performance analysis, whereas the symbols represent the corresponding simulation results.

Table 2. System parameters

Parameter	Value
Transmission power (P_t)	40W
Operating bandwidth	10MHz
Number of PRBs (C)	48
Path loss exponent (α)	4.5
Thermal noise density	-174dBm/Hz
Cell radius (R)	750m
Mean of exponential PDF ($1/\delta_j$)	1
Outage threshold (γ)	-10dB

4.1 Traffic Performance

In **Fig. 4, 5** and **6**, we investigate the traffic performances, such as the call blocking probability, the forced termination probability and the resource utilization. Generally, these numerical examples show that our analytical results are very similar to those of the simulations.

Fig. 4. Call blocking probability vs. offered load with various z

Fig. 5. Forced termination probabilities vs. offered load with various ω

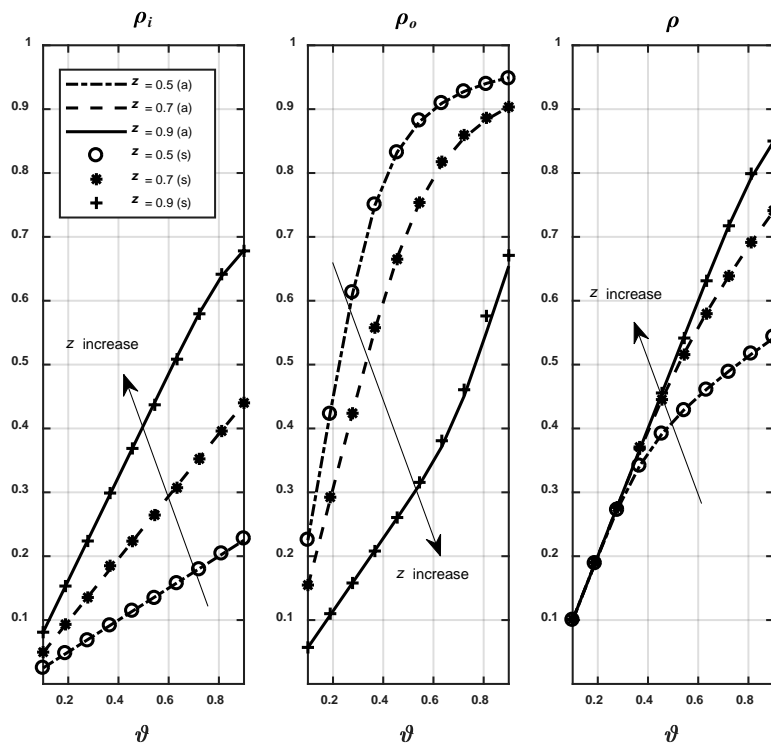

Fig. 6. Utilization vs. offered load with various z

Fig. 4 shows the call blocking probabilities for various offered loads, \mathcal{G} . For the effect of z , as this value increases, P_{Bo} and P_B tend to decrease, whereas P_{Bi} increases, i.e., the blocking probabilities of the inner and outer are not evenly blocked. This is because as z increases, the number of UE reaching the outer region decreases; so, the number of blocked outer calls decreases. For $z = 0.5$, as P_{Bi} is very small, this value is not shown in this figure. For $z = 0.7$ and $\varepsilon_B = 1 \times 10^{-2}$, P_{Bi} and P_{Bo} are satisfied at $\mathcal{G} \leq 0.7$ and 0.2, respectively.

The forced termination probability is plotted in **Fig. 5**. For \mathcal{G} , P_f is very small. As shown, P_f increases as ω increases. This is because as ω increases, the number of inner UE increases, resulting in a decrease in the number of the inner UE that terminate.

Fig. 6 shows the resource utilizations for various offered loads, \mathcal{G} . As shown in the figure, the resource utilizations are not balanced. It is noteworthy that, in Eq. (16) and (17), ρ_i , ρ_o and ρ depend on z . As mentioned earlier, this is because z affects the number of UE arriving in each region. The large z provides a large inner zone and a higher ρ_i , while ρ_o decreases. The outer PRBs are shown to be more heavily utilized than the inner PRBs.

4.2 Outage performance and system throughput

Fig. 7, 8 and **9** show the outage probability and the system throughput of the proposed scheme. In general, based on these figures, our analysis agrees well with the simulations.

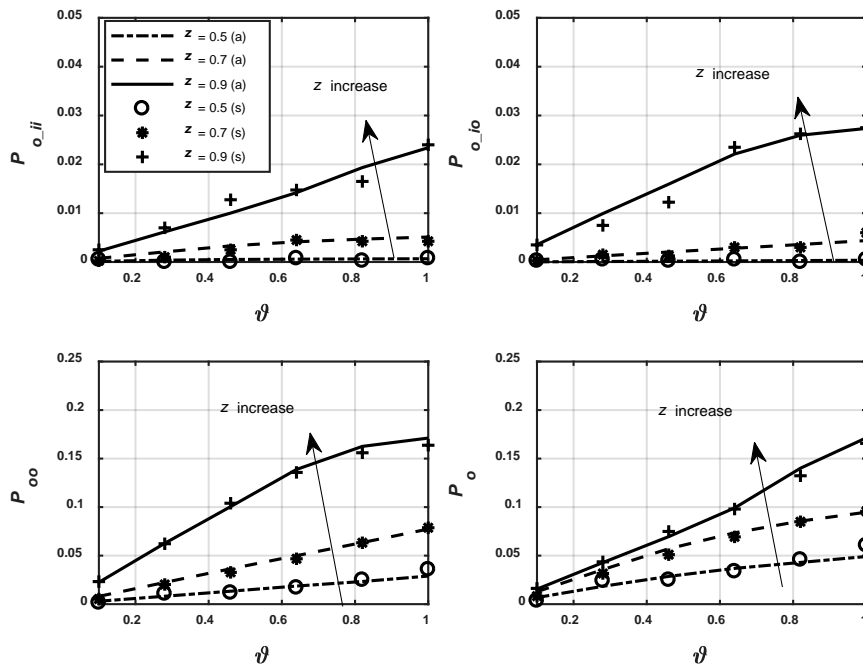

Fig. 7. Outage probability vs. offered load with various z

Fig. 7 shows the outage probabilities for various offered loads, \mathcal{G} . The results showed a significant disparity in the outage probability depending on the type of UE, where $P_{o_{ii}}$ and

$P_{o_{io}}$ are lower than P_{oo} as the inner UE are relatively close to the serving eNB. For the effect of z , as z increases, the outage probability of each UE increases. This is because, as expected from the resource utilization result, an increased inner zone increases ρ and leads to the extended probability that an interference occurs from the neighboring cells. For $z = 0.7$ and $\varepsilon_o = 0.1$, P_o is satisfied at $\mathcal{G} \leq 0.6$.

Fig. 8 shows the system throughput according to the values of various z . In addition, this figure presents the result of Eq. (3). **Fig. 8** also shows that the achievable system throughput depends not only on the offered load but also on the size of the inner area. As shown, at a lower \mathcal{G} , each S_{th} is similar for different values of z . Whereas as z increases, S_{th} increases at higher \mathcal{G} .

Fig. 8. System throughput vs. offered load with various z

The relationship between the system throughput and the outage probability is plotted in **Fig. 9**. Also, **Fig. 9** presents the result of Eq. (4). In this figure, we confirm that the system throughput cannot be increased without increasing ε_o . For example, when $\varepsilon_o = 0.049$ and $z = 0.5$, the system throughput is 0.56. And when $\varepsilon_o = 0.095$ and $z = 0.7$, the system throughput is 0.76. However, for low outage probabilities (i.e., outage probability < 0.05), the system throughput is less than 0.6.

Table 3. Summary of various schemes

	S-SFR	SFR v2	SFR v1
Spectrum handoff	○	X	X
Preemption	○	○	X

Additionally, we compare the performances of our scheme with other ICIC schemes. In Fig. 10, SFR v1 is the scheme shown in Fig. 1 and SFR v2 is the proposed scheme in [7]. In [7], similar to our proposed scheme, an inner UE can use an outer PRB and be forced terminated by an outer UE, whereas an inner UE cannot use the spectrum handoff. Each scheme is summarized in Table 3.

Fig. 9. System throughput vs. outage probability with various z

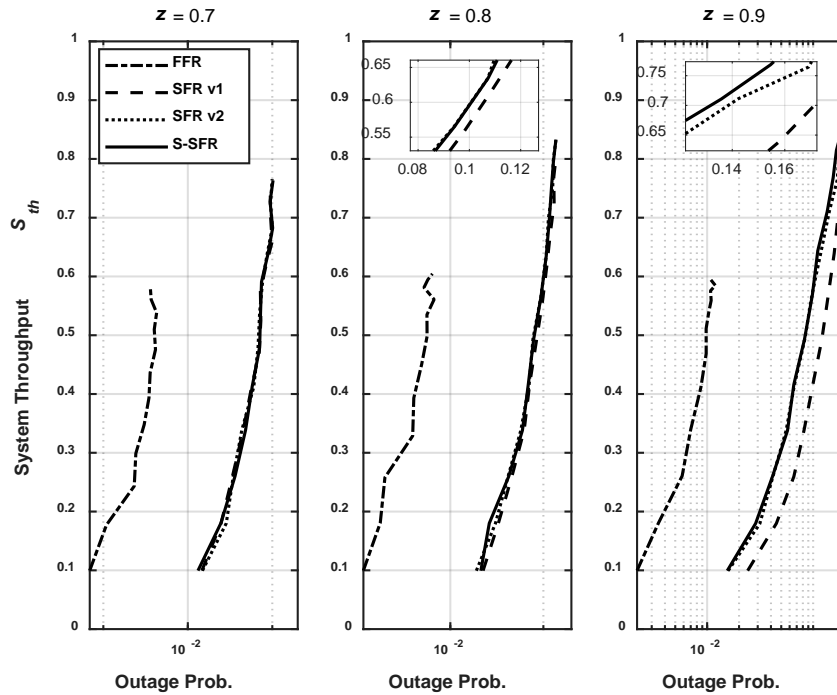

Fig. 10. System throughput vs. offered load with various z and schemes

Fig. 10 shows that at a lower ε_o , the system throughput of the FFR scheme can achieve the maximum value. Whereas for increased ε_o , the SFR-based system can obtain an increased system throughput. This is because, in FFR, some outer PRB is unused, thus leading to the increase in the call blocking probability and the decrement of system utilization. For an SFR-based system, we note that the PRB assignment of the inner UE using all PRBs is more efficient than that of the inner UE using the limited PRB set. In this figure, we observed that our scheme outperforms the other SFR schemes.

5. Conclusion

In this paper, to overcome the problems of the existing SFR schemes, we proposed the analysis model for S-SFR-based OFDMA cellular system. We analyzed the proposed system through performance indicators of outage probability, call blocking probability, system throughput and resource utilization.

In the analytical model, we first used a 2-D Markov chain analysis for traffic performance to obtain the resource utilization and the call blocking probability. Also, we have obtained the closed-form expression of the outage probability, where resource utilization is used for the probability of interference occurring. Finally, the system throughput is derived using the outage probability and call blocking probability. We showed that our analysis results are consistent with most of the simulation results. The results showed that the size of the inner area affects the system performance. The significant result also was found that the system throughput achieves its peak at $z = 0.7$. A tradeoff is observed between the system throughput and outage probability.

Additionally, we compared our scheme with other ICI schemes. The result showed that limited PRB assignment can improve outage performance while deteriorating the system throughput.

Yi-Kang Kim received his master's degree in computer science in 2010 from Korea University, Korea. He is currently a PhD candidate in the Department of Computer Convergence Software at Korea University. His research interests include performance evaluation of communication networks, interference management, 5G network protocol for mobile edge computing, IoT, and SDN/NFV.

Choong-Ho Cho received his PhD degree in computer science in 1989 from INSA de Lyon University, France. He is currently a professor at Korea University in the Department of Computer Convergence Software since 1994. He has participated in various research projects involving an IMT-advanced system, cognitive radio, interference management, energy management systems, and heterogeneous networks. His research interests include performance evaluation of communication networks, energy efficiency, 4G/5G mobile/wireless networks, internet business, ICT convergence, building/home energy management system, smart city platform.

Seok-Ho Yoon received the B.S and M.S degrees in Computer and Information Science in 2009 and 2011, respectively, from Korea University, Korea, where he is currently working toward the Ph.D. degree in the Laboratory for information & communication convergence technology, Korea University. He has participated in various research projects involving an interference management, BEMS (building energy management system), demand response, design and analysis of energy management systems.

Seung-Yeon Kim received his PhD degree in electronics and information engineering in 2012 from Korea University, Korea. He is currently an assistant professor in the Department of Computer Convergence Software at Korea University. He has participated in various research projects involving an IMT-advanced system, cognitive radio, and interference management. His research interests include performance evaluation of communication networks.
